One feature of skin, however, may throw some light on this mechanism of stimulation. Tappemeier and others have shown that light greatly increases the toxicity of certain toxic derivatives to micro-organisms, very many dyes and dyestuffs are similarly affected. All these bodies fluoresce in the presence of light. Traces of haematoporphyrin, which is also fluorescent, can be demonstrated in most normal urines. If haematoporphyrin is injected into animals such as white mice they remain quite normal so long as they are kept in the dark, but exposing them to strong light causes acute pyrexia, the skin becomes very red and inflamed, and death may ensue. Haematoporphyrin has the same action in man. Meyer-Betz injected himself with very small amounts of haematoporphyrin and examined the effects of different light on his skin. Sunlight caused burning on the exposed parts, associated with reddening, swelling, and later pigmentation. A considerable amount of clinical evidence is available showing that certain periodic eruptions, such as summer prurigo and hidradenoma, are directly caused by the action of light, and that the determining condition for this effect is the presence of some unusual substance in the body such as haematoporphyrin. Now one property of these substances which give rise to light sensitivity is that of fluorescence. The light is absorbed and part of the energy used to generate light of greater wave length. This fluorescence is exhibited best under the ultra-violet rays. So we have clear evidence that a non-bacterialidal fluorescent substance may be introduced bactericidal by the influence of light, and when present in the system may render the animal supersensitive to light. Bence-Jones long ago showed that normal tissues and urine contain yet another substance which fluoresces and which can be extracted from the skin by boiling with hydrochloric acid. To this substance he gave the name "quinoidine". It is well known that the normal skin fluoresces blue, but only when the epidermis is intact. In diseases the skin is particularly fluorescent suggesting that damaged epithelium in these conditions is especially absorbent for this substance.

I have pointed out that there is good evidence for believing that light, mustard leaves, and mustard gas ultimately produce their effects in the same way, therefore it might be argued that those who are tolerant or supersensitive to the one stimulant should be so also to the other. This is definitely not the case, and the reverse is not uncommon, though negroes are tolerant to all three this suggests that some other factor may be necessary to produce erythema apart from the light. This factor might well be of the Bence-Jones quinoidine, since it is known that skins of the supersensitive are particularly fluorescent, and that fluorescent substances under the influence of light exhibit remarkable properties, such as the artificial production of supersensitivity. This view is entirely different from that expressed by Dr. Peacock, speaking recently in the name of Professor Russ and himself, in which he regarded the fluorescence of the skin surface as a protective phenomenon, though on what evidence I do not know, except, of course, that outside the body fluorescent substances absorb ultra-violet rays.

General Action of Light

The general systemic action of light stimulation of the skin bears close similarity to that of other forms of skin stimulation. A mustard leaf causes a slight stimulation of the heart, slight splanchnic vasoconstriction with a corresponding rise in blood pressure, and some increase in respiration. These effects are all produced reflexly through the medulla. Metabolism is slightly increased, the absorption of oxygen, carbonic acid output, and nitrogenous excretion are all augmented, but the last only slightly. The general immunity is also increased. All these effects are said to be produced by the stimulant action of light, though the experiments of L. Hill on man are open to other interpretations. It must, however, be remembered that we are dealing here only with the action of light on the skin and are not concerned with the shortest ultra-violet wave-lengths which readily kill infusoria and bacteria, but which are unable to penetrate the undamaged skin and therefore do not cause erythema.

One other effect of both chemical skin irritants and light is the deposition of pigment in the skin. Little is known of the mechanism of its production, but its formation is in no way specific to light. Arsenic among other drugs causes pigmentation of the skin, the pigment in these cases is a degradation product of haemoglobin, but we are in ignorance as to why it is deposited in the skin, though certainly here it is not concerned with light. But arsenic is excreted by the skin, promotes growth of the skin, and, like light, acts as a mild irritant, continual irritation of the skin with mustard also leads to pigmentation indistinguishable from that of light. The function, however, of light pigmentation can hardly be doubted, it is an absorbent for ultra-violet rays. Half an hour's irradiation of cholesterol suspended in water renders it antirachitic, but if the water is coloured by carotin the activation fails. It is suggestive that one function of pigmentation is to absorb such solar waves (ultra-violet) as are not, under the conditions obtaining, required by the body. Cholesterol, which is plentiful in the skin, becomes yellow after the prolonged action of ultra violet rays and may play some part in the coloration.

Specific Action of Light

But besides this general action, light has another and more specific effect. Ultra-violet light influences the storage of calcium and phosphorus and their equilibrium, not only in growing, but in mature animals. Growing rats subject to daily irradiation by the mercury quartz lamp increase in weight and then total calcium content goes up considerably in excess of the controls.

An abundance of evidence is now available to show that ultra-violet radiations from the sun or, better, from the mercury vapour lamp protect children from rickets or cure the disease when its effects are already evident. Something is known of the method by which this is produced. If young rats are placed on a diet which readily produces "rickets" the disease can be prevented by subjecting the animals to ultra-violet rays for two minutes daily at a distance of three feet from the lamp. This action might conceivably be produced by an effect of the rays either on the animal or on its food. Reasons exist for believing it is on both. Many entirely different substances subjected to ultra-violet rays assume antirachitic properties which they did not previously possess. Wheat, biscuits, flour, meat, milk, eggs, as well as such fats as olive oil, lard, cottonseed oil, and linseed oil, can readily be activated so as to become antirachitic. One substance which is widely distributed throughout nature, present indeed in almost every animal cell, and therefore in all the foodstuffs named, is cholesterol, and this substance in the pure crystalline state becomes antirachitic after irradiation with the mercury vapour lamp like the foods named. Unlike foods, however, this irradiated cholesterol in a dry state rapidly loses this property unless it is dissolved in oil, when its curative properties are retained. Practically all oils contain cholesterol or its allies, and some of them, like the fish oils, possess natural antirachitic properties, but all of them have the faculty of becoming antirachitic after irradiation, and the curative virtues when once

established are not easily lost by keeping. It is generally believed that foods possess antirachitic properties by virtue of their cholesterol content. Hess has shown recently that ultra-violet rays change the chemical nature of cholesterol, its spectrum is altered and it becomes more transmissible for ultra-violet irradiations.

The skin is especially rich in cholesterol, and it has been shown that rats placed on the standard rickets-producing diet, low in phosphorus, do not contract rickets if they receive a small ration of irradiated skin of some animal. Hess thinks that such experiments show that the antirachitic effect of ultra-violet light in man is due to the activation of the cholesterol in the superficial layer of the skin. As this effect can be produced in the test tube, and is apparently independent of the bodily functions, it may be due to some definite chemical change. This property—that light can produce chemical substances in the skin which are preventive and curative for rickets—forms an important factor in its action. Such daily doses as 1/100 grain of an activated cholesterol protects experimental animals (rats) from the changes produced by rickets in a vitamin-deficient diet.

Two other points of practical interest require consideration. The first is that too long an exposure of cholesterol or food substances containing it to ultra-violet light renders them inert as a remedy for rickets, though this is unlikely to happen from continuous irradiation of the skin, since before this stage is reached pigmentation would occur and the pigment absorb the ultra-violet rays and render them inactive.

The second point is that such information as we possess suggests that there is no close relationship between the incidence of rickets and sunshine. In the Panama Canal zone, where rickets hardly exists, the yearly sunshine is not only less but is less evenly distributed than in New York. Some authorities state that effective solar radiation is so small in the winter that even if we were to substitute quartz panes for window glass it would be inadequate as a protection from rickets. In other words, light cannot be substituted for the older preventives like cod liver oil. It may be, as Dr. Leonard Hill has pointed out, that the smoke cloud which hovers over large cities absorbs much of the ultra-violet light in these places. It has been shown in America that during the winter months, when exposure to sunshine out of doors is difficult and the ultra violet light in the solar spectrum at a minimum, such sunshine as is available is insufficient to prevent rickets in rats.

These experiments show that, apart from therapeutic action in disease, ultra-violet rays can produce a chemical change in the tissues.

At present we have no satisfactory way of measuring the dosage of ultra-violet radiation, but there is some clinical evidence suggesting that overuse leads to diminished immunity. Sunshine is not a universal panacea in disease, and in health most of us try to avoid it. In Sweden, where clinical experience of light treatment is considerably greater than our own, it is clearly recognized that many people are unsuitable for such treatment, particularly is it the case with neurotics and the highly reflex.

II—C E M JONES, M B, B Ch,

Senior Assistant Medical Officer, Lord Mayor Treloar Cripples' Hospital, Alton, Hants

THE CLINICAL ASPECT

The two conditions in which light treatment has been found clinically to be of the greatest value are those of rickets and non-pulmonary tuberculosis. In regard to rickets, it is known that children and animals sufferings from this disease can be cured in a few weeks by exposure to light for a few minutes daily, also, in the case of animals experimentally fed on a rickets-producing diet, the disease may be considerably postponed, if not totally prevented, by similar exposure to light. In a case of rickets the deficiency of calcium and phosphorus, which is demonstrable in the case of the former substance by a skatogram, can be shown to be made good.

In discussing the value of light treatment in non-pulmonary tuberculosis, I would desire to emphasize the fact that, especially in bone and joint lesions, light is merely an adjunct method of treatment, which should be combined with general and local measures. There are some who appear to regard light as a specific cure for tuberculosis. Such a view is misleading, while it is an auxiliary method of treatment of the greatest value, the idea that bone and joint tuberculosis can be cured by light alone, without the employment of conservative methods of treatment involving general and orthopaedic measures, is fantastic.

Light acts in two ways: it has a local action and a general action, and in discussing the action of light I will, for purposes of convenience, deal separately with treatment by natural sunlight, or heliotherapy, and treatment by artificial light.

Heliotherapy

Local action.—Light has direct bactericidal action and has the power of destroying certain bacteria on the surface of the part exposed, it also acts by producing an inflammatory response in the exposed region. A sinus exposed to light at once commences to discharge more freely, the discharge is less purulent and more serous, and small sequestra are sometimes extruded.

General action.—The general or remote effects of light are of much greater importance. In suitable cases it produces a feeling of exhilaration and increased well-being, combined with increased metabolic activity. What is meant by the words "in suitable cases"? All patients do not benefit by heliotherapy, some do not benefit at all, and, in fact, are harmed by it. The benefit which a patient derives from sun treatment appears to be associated with his power of pigmentation, this statement is not accepted by some workers, but is one of the clinical truths of which I am firmly convinced. It is a matter of common knowledge that dark-haired people pigment better than those who are fair, and that the latter tend to blister and burn rather than to pigment when exposed to the sun. The most typically non-pigmenting person is, perhaps, the sandy-haired, freckled individual, this type, when exposed, instead of being stimulated and exhilarated, becomes depressed and collapsed. It is therefore necessary to decide in each individual case whether or not the patient is suitable for insolation. Further, in cases which are suitable for sun treatment, the exposures should be carefully graduated, in order to avoid overexposure and resulting depression and collapse. For example, on the first day the legs from the feet to the knees should be exposed for five minutes an hour for three consecutive hours, the area exposed and the time of exposure should be gradually increased, so that after about ten days the whole of the body may be exposed for about twenty minutes an hour for three consecutive hours. By this time the patient should have become fairly well pigmented, and when this is the case longer exposures can be tolerated with comfort. The head should always be protected from the sun, and the patient should never be allowed to feel either too hot or too cold, he should always feel invigorated and never be allowed to become tired or exhausted. The feeling of exhilaration produced by exposure to light is a condition with which, speaking generally, we are all familiar, and those who have had experience of institutions where heliotherapy is systematically and correctly practised cannot fail to be struck by the cheerful condition and optimistic outlook of the patients. This psychological phenomenon is combined with a condition of increased metabolic activity: this increase of metabolism is a measurable factor. Research work on this subject has been carried out at the Lord Mayor Telford Cripples' Hospital at Alton by Dr. Argyll Campbell and Dr. Leonard Hill, of the National Institute for Medical Research, working in conjunction with Sir Henry Gairdner. It has been found that in spite of the fact that children at Alton were recumbent and immobilized, their metabolic activity was about 40 per cent higher than that of an ordinary child. This was attributed to their exposure to the air and sunlight. In addition to this physical condition of increased metabolic activity there is also apparent an increase in mental activity which is produced on exposure to sunlight and air. In this connexion I would like to refer to the tests carried out by Mr.

C. R. Macdonald of Melbourne, in collaboration with Sir Henry Gairdner, which formed the subject of a paper read by Sir Henry Gairdner before the Royal Institute of Public Health in congress at Brighton. Stated briefly the results were as follows. Mental tests were applied to children in special schools for the physically defective in London, and to patients at Alton. It was found that the children at Alton were mentally nearly a year in advance of the London children. After excluding such possible factors as heredity, superior educational facilities, and differences in the severity of physical defects, none of which were found to be applicable, the conclusion arrived at was that the superiority of the Alton children was due to the treatment received in the hospital, while the increased metabolic activity already referred to would be likely to cause improved mental activity, it was considered that it would be unlikely that this was the full explanation of the mental superiority of the Alton children. The interesting suggestion was advanced by Sir Henry Gairdner that ultra violet light might improve the nutrition of the grey matter of the brain, even as it induced bone repair in the case of rickets.

There are two points of interest in connexion with heliotherapy in non-pulmonary tuberculosis to which I would like to refer. The first is connected with the question of pigmentation in the case of a patient suffering from bone and joint tuberculosis, if the lesion becomes quiescent following treatment, and if the patient is a non-pigmenter, then it is probable that there is latent tuberculosis in that patient, and he will either have a recurrence or develop a new lesion, if a new lesion should occur, and be treated, then the patient frequently develops the power of pigmentation and his subsequent progress is more satisfactory. Power of pigmentation may thus serve as an indication of prognosis. The second point which I would like to mention is the effect of sunlight and air on the musculature of the patient. Patients treated in this manner are relatively free from the muscular wasting commonly associated with bone and joint tuberculosis, and this is of obvious advantage to the patient when the stage of ambulatory treatment commences.

Artificial Light Treatment

Artificial light treatment is, of course, employed as a substitute for heliotherapy when natural sunlight is not available, either owing to climatic conditions or when suitable sites for the employment of heliotherapy are lacking, as in congested areas in large towns. Much valuable work is done in light clinics by giving artificial light baths to rickets, debilitated, and pre-tuberculous children, in crowded slum areas. In the treatment of non-pulmonary tuberculosis artificial light treatment differs from heliotherapy in one important particular. Whereas in heliotherapy we have seen that it is the general effect of light that is important as compared with the local action, in artificial light treatment of the cases the part played by local treatment is of far greater importance, though here also it should always be combined with general treatment.

In an artificial light department general light baths are usually given either by means of the carbon arc lamp or by some form of mercury vapour lamp. Certain advantages can be claimed for each of these two methods. The light from the carbon arc more closely resembles natural sunlight and possesses greater power of pigmentation than that of the mercury vapour lamp. On the other hand, longer exposures are required. A commencing dosage of twenty minutes to half an hour might be given with a carbon arc lamp whereas three minutes with a mercury vapour lamp would suffice. The arc also gives out a fairly considerable amount of heat which is apt to become exhausting to young or debilitated patients, and for this reason the mercury vapour lamp is sometimes to be preferred in cases of these types. Some workers prefer to use the carbon arc, while others favour the mercury vapour lamp. Personally I much prefer the arc for the purpose of general light baths. An interesting point in connexion with carbon arc is that it may be employed with caution in the treatment of cases of cases which cannot be exposed to natural light. Such cases will often acquire a certain amount of pigmentation.

the protective action of which will enable them to tolerate some exposure to natural sunlight, with its corresponding benefits.

I have mentioned previously that, in the treatment of non-pulmonary tuberculosis by artificial light, local treatment plays a relatively more important role than in the case of heliotherapy, and cases of lupus, scrofuloderma, skin tubercles, glands in the neck, sinuses, etc., are greatly benefited by local treatment by light relatively rich in ultra-violet rays. Thus, lupus in the ulcerative stage is advantageously treated by the mercury vapour lamp, when the ulceration has healed the treatment must be completed by the Finsen-Reyn lamp, which is usually essential for the final eradication of the disease. Scrofuloderma may be treated by the mercury vapour lamp or the tungsten arc, skin tubercles by the mercury vapour lamp, glands in the neck, more especially those of a multiple nature and accompanied by paradenitis, are greatly benefited by the tungsten arc. The Kromayer water-cooled mercury vapour lamp is useful in certain stages of the treatment of lupus. The quartz rod applicators are very helpful in the treatment of lupus in such situations as the interior of the nose, the gums, rectum, vagina, etc.

As an illustration of the advantage of combining general treatment with all forms of local light may be mentioned the results obtained at the Finsen Institute at Copenhagen. It was found that in the case of lupus patients given local treatment alone the percentage of cures was 60, whereas in the case of combined general and local treatment the percentage of cures was 80.

Contraindications to Light Treatment

It has already been mentioned that non-pigmenting persons are unsuitable subjects for heliotherapy. Others in which it is contraindicated are pyrexial cases, cases of marled amyloid disease, the acutely ill, the very young and the aged.

It has been stated above that in unsuitable cases light treatment produces depression instead of stimulation. This condition of depression is also produced by overexposure in cases otherwise favourable. It has been found that after exposure to light a rise in the haemo-bactericidal power of the blood is demonstrable, which persists for a few hours and then returns to normal. It has been shown by Dr R. G. Brunnerman, the research pathologist at Alton, that an overdose of light, such as an initial exposure of half an hour to the mercury vapour lamp, produces a rise in haemo-bactericidal power which not only returns to the normal, but which may fall below the original level and remain below it for some time before gradually rising to the normal. This was found to be accompanied by certain other phenomena, notably an increase in the rate of sedimentation of blood corpuscles, which is taken to indicate a phase of diminished resistance. This apparent lowering of resistance may account for the condition of depression which is produced by the exposure to light of unsuitable cases.

III—G. H. LANCASHIRE, M.D.,

Honorary Physician, Manchester and Salford Hospital for Diseases of the Skin

PHOTOTHERAPY IN DERMATOLOGY

THE treatment of skin disease by physical means is a field that has been greatly extended in recent years. Electricity, heat and cold rays, and light have all been exploited. With regard to ray therapy it has taken the accumulated experience of twenty years and more, since Schiff and Freund published their pioneer work on the subject, to enable one to say what are the indications and the limitations of the method in dermatology. It may well be the same with the later developments in phototherapy, and it must be borne in mind that these are but developments of the ideas given to the world by the genius of Finsen.

At our skin hospital in Manchester we were early in the field with Finsen's lamp, and only discontinued treatment with this and Reyn's modification after several years. Economic reasons, and the difficulty of getting efficient help

for its exacting service, were the chief motives for the change. Nevertheless the results in suitable cases of lupus vulgaris were good, and have perhaps never been bettered from a cosmetic standpoint. In September, 1924, we installed at the hospital in apparatus for artificial sunlight treatment, and in this matter we owe our grateful thanks to Dr. Sequerra and Dr. O'Donovan of the London Hospital for their willing help.

In our temporary room at the hospital we have two carbon lamps of the high ampere pattern, which are burning in parallel at 25 amperes each, in order to obtain an intense irradiation for treating six to eight patients simultaneously or two recumbent patients at one time. The ordinary plain electrodes are used, containing no metallic or other chemical elements. The upper carbon (positive) is coiled, and the lower carbon (negative) is solid, producing a long and brilliant arc flame. We have begun treatment with half-hour exposures, gradually extending the exposure to three hours daily. We have obtained the usual reactions, which have been already described by writers. We use also a powerful ozone apparatus, as is usual, in conjunction with the arc lamp. It will be noted that we have not used a single lamp of very high ampere, but two lamps of lower power side by side. This appears to have been a misadventure, but it has proved effective. The temporary room we have been compelled to use, pending new buildings, has been by no means ideal. The question of ventilation for such a room is of high importance, and the difficulty is that air currents may disturb the arc flame. Probably a lofty room with exhaust fans on the roof would be best.

The artificial sunlight treatment has been reserved for tuberculous skin cases, mostly lupus vulgaris, and the irradiation has covered the whole body surface, the "light bath" the lesions themselves in most cases being covered. I may say at once that the results we have obtained have exceeded my expectations, and that I believe this method is a real advance in our treatment of lupus, especially in the widespread and severe cases that we see in Manchester. It is possible that we shall do still better when we combine general with local irradiation, but the former alone has given us some fine results. It would take too long to describe individual cases, but in addition to the improvement in skin lesions there have been several showing wonderful improvement in lupus of the buccal and nasal cavities.

Reyn, who read a paper before this Association in 1923, said that light baths alone would not cure lupus without the local application of concentrated light. He might modify this view at the present day. At the same meeting Sequerra confirmed the opinion of Strandberg that intra-nasal lupus may be cured with the light bath alone. There seems to be no theoretical reason why lupus of the skin should not be included in the same category.

In common with others we find that the light bath improves the general health and well-being of the patient, who usually gains weight in the early stage. The cosmetic results are, as would be expected, extraordinarily good, this being a "natural" cure. A word, however, in conclusion on the question of lupus. The success of this light treatment does not imply that all older methods must go by the board. Economic reasons alone will necessitate the employment for some time to come of more rapid and less expensive methods. An active lupus threatening the eyesight, too, is justifiably tackled more vigorously.

Coming now to the direct application of ultra-violet rays to skin disease, my own experience, since the Finsen lamp epoch already mentioned, has been confined to the use of the tungsten arc apparatus. I am not qualified to speak of the mercury vapour or other forms of lamp, but on theoretical grounds the open tungsten arc should meet requirements, and I believe that in practice it does so. Unfortunately my experience has been only short. I have used the tungsten arc mainly in the treatment of the seborrhoeic type of alopecia and alopecia areata. In the latter condition I have already obtained some striking results, notably so in the case of an adult with complete baldness of two years' duration, the scalp being smooth, shining, and atrophic-looking. In this case there has been a growth of hair half an inch in length on the crown within two months. I am aware of the great danger in alopecia areata of ascribing results to treatment. *Vix medicatrix*

naturae would probably heal a large percentage of the cases which we have in hand, as indeed it sometimes does in cases which we have abandoned as hopeless. I have in mind two gentlemen, each over 70 years of age, whom I saw many years ago. One had rapidly spreading alopecia areata involving the whole scalp and leaving a few hairy islands only. The other had a big band of alopecia (ophiasis) on the occiput. In both patients the bald areas were atrophic and showed no follicular site. After a good trial treatment was abandoned. The gentlemen returned a year or so later, to confound me with a good growth of hair and no signs of abnormality. This would have been a triumph for phototherapy had it been known in those days. Despite the difficulty of separating the *post* from the *propter hoc*, however, the results seem too uniform to be ascribed to chance, and I believe that in some way, probably by stimulation of the capillary circulation, ultra-violet rays do promote the growth of hair. It is more than likely that visible rays also play an important part, since these rays penetrate more deeply. Another factor in the case of the tungsten arc may be heat, which is appreciable. At hospital we used for a long time a lamp of which the chief output was heat, and in some cases there appeared to be good results. In this connexion I may perhaps mention that you, Mr President, once observed that there might be some therapeutic value in the use of heat rays alone in dermatological practice. Although I have other cases of skin disease under the local application of ultra-violet light I prefer to make no comment on these pending further experience.

In recent publications many skin complaints are stated to be curable by phototherapy. I trust a good case is not being spoiled by too wide a claim. Although in the interests of research it may be allowable to investigate a wide field, the treatment should really be reserved for those things which it can do better than other methods. If, for example, it can be proved to relieve the troublesome cases of pruritus one often meets—cases unaccompanied by visible lesions—practitioners will be glad to adopt it in place of x-ray therapy, which, though effective, is always, or should be, attended by some anxiety.

One would be inclined on theoretical grounds to doubt the efficacy of local phototherapy on the deeper-seated psu-coeal skin affections, since we are told that the penetrative portion of ultra-violet rays is non-bactericidal. On the other hand, phagocytic action may in some way be stimulated. I would prefer to treat impetigo contagiosa on the old lines. I would like to know the reason for light treatment in ringworm of the scalp, and in rodent ulcer. For the latter disease we already have reliable weapons in x-rays and radium, augmented by diathermy for involvement of hard parts. Phototherapy is advised also for *acne vulgaris*. One may note that acne in town dwellers is often improved by a holiday in the sunshine, but the change, of course, may be due to the improvement in general health. *Cerebra*, *reute* and *chronic*, is also mentioned as suitable, we know that sunshine always aggravates the disease.

I have no wish to depreciate the value of the work of others who have had longer experience than I, but I think it would be well to publish further evidence before advising the method in so many and widely dissimilar skin affections, otherwise discredit may fall on what is a real advance in therapeutics. In some skin diseases phototherapy would be definitely contraindicated. This group would probably include lupus erythematosus (though in one case of this disease I have obtained improvement by the light bath, the lesion itself being covered), and would certainly include those diseases which have been actually initiated by light rays themselves.

Sir Lenthal Cheble wrote in the *JOURNAL* of March 28th last (p. 631) that there might be a tendency in ultra-violet radiation towards malignant changes in the skin, especially if the skin already suffered from an irritant such as tar. Subsequent writers negatived this idea, but it is one which should be noted, and which time alone can refute. The history of x-ray treatment prevents one from dismissing it too lightly.

In conclusion, I believe that though the value of phototherapy, local and general, has been abundantly proved for tuberculous skin diseases, more experience is required to establish its real worth in other departments of dermatology.

GENERAL DISCUSSION

Dr W MITCHELL (Bradford), as one who had been doing this work since 1906, thanked Professor Dixon for his most illuminating paper. The main conditions with which he himself had been concerned were lupus, tuberculous glands, alopecia areata, tinea, acne, and lupus erythematosus. In spinal tuberculosis in children he had had very good results from general treatment. Tuberculous glands did very well, but it was quite useless to treat them with light if an abscess was present. Lupus cases also did very well, a preliminary dose or two of filtered x-rays was a great help. In lupus erythematosus he had had good results with ultra-violet rays. He described a case of universal alopecia areata treated successfully, so far as the return of hair to the scalp was concerned, by weekly exposures to the Kromayer lamp. Acne did fairly well, but for this condition he preferred filtered x-rays.

Dr P HEFFERNAN (Buxton) asked a question regarding the effect of light on metabolism. In Derbyshire there was always a certain amount of endemic goitre, generally attributed to iodine starvation in infancy and childhood, but this endemic goitre was known to be intimately associated with the dark narrow mountain valleys with a limited horizon, where the inhabitants were deprived of a great deal of direct sunlight. Apparently the Swiss, by the administration of iodine in the schools, had very considerably reduced the incidence of endemic goitre in the children. Professor Dixon had said that it was not possible to increase the calcium or phosphorus content of the tissues by feeding by mouth, but there might be something in the action of direct sunlight on plants used for food. Dr Heffernan took it that in this matter of food there was an irreducible minimum below which definite starvation symptoms would appear. He desired to know from Professor Dixon whether there was any relation between the amount of direct sunlight on plant life and the power of the plants in fixing iodine.

Dr R GARROOD (Huntingdon) offered the suggestion that one of the factors accounting for the difference between the action of light on pigmenters and non-pigmenters might be racial type. He thought that in the mixed composition of the English people there was a good deal of Mediterranean blood, and he believed that the Mediterranean type survived the risk of tuberculosis much better than the purely Nordic type. It had even been suggested that under modern factory conditions they were returning to a cave-dwelling environment, and so a more primitive type survived.

Dr E P CUMBERBATCH (London) asked whether advantages were to be gained by using carbon impregnated with various metallic salts. He took it that the duration of exposure necessary for obtaining the erythema dose would be lessened if carbon impregnated with nickel or other metals were used. Was there any advantage in a twenty minutes' exposure to the carbon arc as opposed to exposure for two or three minutes to mercury vapour?

Dr NEWMAN NEILD (Bristol) thought that some warning was necessary against injudicious exposures of phthisical patients to sunlight. He had seen two cases recently in which the whole chest had been injudiciously exposed. It was necessary to keep a careful watch on patients when they started using this method. With regard to the supposed uselessness of calcium by the mouth, Professor Dixon spoke as a pharmacologist, the speaker had seen it do good. The fact that it was not absorbed did not imply that it was of no use.

Dr HELEN MACKAY (London) said that with regard to neurotic patients her impression was that the vast majority of children suffering from irritability and general discontent responded well to light treatment if it was carefully graduated. Almost invariably the mother of such a child would state after a fortnight or three weeks that the child was infinitely happier. But, in young children, if the dose was put up too quickly the child, who is happy enough, would not go to sleep at night. A day or two

after cutting down the dosage the child would be found to sleep quite well again. In the case of extremely young children she had over and over again got in extraordinarily good effect on the general condition, but it was necessary to go more slowly than in the case of older people. She believed also—although she had had no experience herself—that radiologists were unwilling to take on the cases of babies and very young children suffering from ringworm of the scalp.

Dr J M H MUNRO (Bath), after a reference to the light installation at the Corporation Baths, asked from the experts some more definite information as to the raising of the haemo-bactericidal power of the blood by irradiation.

Dr T B POOR (Westchiff-on-Sea) said that the point with regard to the absorption of calcium had impressed him very much. Some while ago an obstetrician saw a case of his of severe metrorrhagia, and advised the giving of calcium lactate prepared freshly from calcium carbonate and lactic acid. This had proved very efficacious and he had used it in a number of conditions, including chilblains.

Dr C F M JONES said, in reply to Dr Cumberbatch's question, that he did not think there was any superiority or advantage in the twenty minutes' or half-hour exposure to the carbon arc as opposed to the two or three minutes' exposure to the new rays upon Clinically he preferred the carbon arc because it more closely resembled the natural sunlight. With regard to Dr Munro's question about the haemo-bactericidal power of the blood, what he had said was that a fall took place as a result of an overdose. What he believed occurred as a result of a properly graded therapeutic dose was a rise, which was maintained, he thought, for three or four hours, but he could not help feeling that this haemo-bactericidal rise was one of more theoretical than practical interest. In rabbits the bactericidal power was, to start with, low—about 50 per cent—whereas in man the average was somewhere between 95 and 100 per cent. Clinically it was found that patients who presented a high bactericidal power did not do particularly well. The question of this bactericidal power was interesting, but practically he did not think it was going to be of very great importance. He added that it was possible gradually to acclimatize so-called non-pigmenting patients to natural sunlight by giving them small doses with the carbon arc.

Professor W I DIXON said that the Section ought to be congratulated upon the fact that so many people with divergent views had expressed their opinions in a very definite manner. Dr Jones had said that clinical results were not always to be explained by science, the speaker agreed. Science must be the servant of the physician. Dr Jones had also said that pigmentation varied with the resistance of the individual. Dr Greenwood had attempted to give him an explanation, and, curiously enough, they were both of them in agreement with Charles Darwin. Charles Darwin, speaking of the colour of the Africans, produced evidence to show that it was only those people who became black who were resistant to certain diseases and so were able to live. This, he took it, was roughly the view which Dr Jones held with regard to one object of pigmentation. No one knew yet entirely why pigment was formed. Dr Jones had referred also to the fact that light increased metabolism. That was a point which was perfectly well recognized, and if metabolism was increased the feeling of well-being was increased also, and one would expect mental activity to be quickened. When Dr Jones suggested as he did that this might be due to the action of light on the grey matter it sounded like a fairy tale. He did not see how light could get at the grey matter. If Dr Jones meant that a stimulation of the periphery caused the reflex stimulation of the brain he would agree, but any direct action was inconceivable to him. There had been some talk about the difference between artificial light and natural light, and he was sorry that the experts who were dealing with this matter did not make their points clear and state the amount of ultra-violet light which was present in sunlight. Some authorities said that sunlight contained 4 per cent of ultra-

violet and one went up to as much as 12 or 13 per cent. But it was known that the only light of this character which penetrated the skin, and therefore produced the beneficial effects, was the shorter rays of the visible light and the longest rays of the ultra-violet. In the case of the short ultra-violet rays the penetration was negligible but it was the short ultra-violet rays which produced the bactericidal action and which killed the protozoa. One other important point which had come out in the discussion was made by Dr Limeshure and Dr Mitchell, that when one wanted to treat a patient for a skin disease it was not necessary to treat the lesion itself. In the case of the eye, for instance, it was impossible to treat the lesion. In the modern treatment of lupus the patients were treated at one time in the back and at another time in the chest, and the condition was cured without touching the lesion at all. The benefit, therefore, must be the general effect, together with that specific action of light to which he had referred in his opening remark. Professor Dixon went on to say that he had been asked about the influence of light on iodine metabolism. It was stated that in Derbyshire and in Switzerland people were liable to get goitres as the result of iodine deficiency. Had the light a certain influence in fixing the iodine in plants or in altering the body tissues so that the body could make use of the available iodine? He did not know that there had been any observations on that. It was known only that simple goitre was due to iodine deficiency. It was a hypertrophy of the gland in order to fix and make up in quantity what the gland lacked in quality. He was sure that the disease on had wandered to calcium, for that had nothing to do with light. Dr Neild had warned them against the pharmacologist but the speaker did not think the warning was necessary. The pharmacologist was not there to dictate, only to give the facts from which the clinician could draw his conclusions and prescribe anything he chose. It was not possible to increase the calcium in the blood by taking calcium by the mouth—that was to say, in normal people by the administration of calcium by the mouth the clotting power of the blood could not be increased. The effect of overdosing was mentioned by Dr Midgley. They all knew that every stimulation was followed by a depression. If the stimulation was enormous to begin with the depression came on quickly. At the present time there were no means of exactly gauging the dose of ultra-violet rays to be administered. It was possible to do this with x-rays, and in the course of time he did not doubt it would be possible to gauge the amount of ultra-violet light administered.

THE USES OF POSTURE FOR BRONCHIAL DRAINAGE

BY

NTWMAN NFILD, M B, M R C P,

Physician Bristol General Hospital

In order to drain the bronchi by gravity, the patient must be placed in such a position that the bifurcation of the trachea is lower than both bronchi, and this result may be obtained in three practicable positions. In all three the thorax is placed at such an angle with the horizontal that both bronchi drain into the trachea as long as this is secured, the patient may lie on his back, face downwards, or on his side.

Lying on the face or back the angle which the line of dorsal vertebrae makes with the horizontal does not require to be so great as when the patient lies upon his side, and therefore the drainage position on face or back will not entail such a pressure of blood in the head as a lateral posture causes. That is certainly an advantage, but the disadvantages in most cases outweigh this advantage.

Lying on the back the fluid drained from the lungs collects in the pharynx or nose, and it is not easy for the patient to get rid of the fluid, should the patient be unconscious this objection to the dorsal posture is still greater. Moreover, it is very difficult to put the pelvis and thighs in a comfortable position.

Less open to objection is the face-downwards position. The chief disadvantage is that the expansion of both lungs is greatly interfered with and it is more difficult to get

the head and neck in a comfortable position. It is easier to obtain this position when the head of the bed can be removed, or on an Illey couch, or sofa with only one upright end. The advantages of this posture are that there is free drainage through the mouth without blocking the nasopharynx, and the base of the lungs is more easily drained without requiring such a steep slope as the lateral posture necessitates.

The lateral posture for bronchial drainage requires a greater angle between the line of dorsal vertebrae and the horizontal. When the patient is lying upon the front or back the bronchi are practically in the same plane as the trachea, from the point of view of drainage, but when the patient is lying upon one side the bronchus on that side, coming off at an angle with the trachea, is lower than the bifurcation, and in consequence the angle which the line of the dorsal vertebrae makes with the horizontal must be made more steep in order that the lower bronchus shall drain properly.

The angle required is greater when the patient lies upon his left side than when he lies upon his right, owing to the fact that the right bronchus deviates less from the continuation of the line of the trachea than the left bronchus deviates. If the patient is lying on his left side, then the angle between the dorsal spine and the horizontal may require to be at least 45 degrees. But the necessity for such a steep slope of the chest is avoided by turning the patient somewhat over towards the face down or upon the back position. The former inclination is more comfortable for the waist and hip-joints, and the latter inclination more comfortable for the head and shoulders.

To place the patient in this position, the pillows and bolster are removed from the bed, and the patient lies upon, say, his right side with the hip- and knee-joints somewhat flexed. The doctor sits on the edge of the bed in front of the patient's abdomen, and facing the head of the bed, then passing his right arm well under the patient's waist near the iliac crests, he lifts the patient's waist rather higher than is necessary to obtain the required angle, while helpers pack pillows and cushions under the patient in order to build a firm double-inclined plane under the shoulder, chest, waist, and thighs. The highest point of the double-inclined plane should be under the lowest ribs, and the apex of the construction must be well rounded off so as to ensure that the pelvis and thighs rest upon the inclined plane opposite to that upon which rest the thorax and shoulder. By this means the patient is without difficulty secured from slipping downwards towards the head end, and also the pressure of blood to the head is lessened.

The patient's head should lie upon the right ear and the mouth be just beyond the edge of the bed. The point of the shoulder should rest upon the lower end of the inclined plane and the corner of a pillow tucked under the neck from behind. The patient's comfort depends very largely upon the position of the shoulder and the support of the neck. Pillows are now adjusted behind the scapulae to maintain the forward or backward addition to the lateral posture and the forward addition should be tried first.

Should it be found that the bronchial drainage angle is insufficient, then the foot of the bed must be raised sufficiently to procure the proper angle, but this adjustment must be left to the last.

I have spent some time in describing what I believe to be the best posture, both for efficiency and comfort should the drainage be required over a long period or frequent periods, because the success of the manoeuvre depends upon the correctness of the posture. If the necessity for drainage is confined to one side of the chest only, then that side of the chest must be uppermost and care taken that the bronchus on the lower side is at a drainage angle, in order to avoid aspirating into the clear bronchus the discharges from the draining bronchus.

There is one condition where it is absolutely imperative that a free drainage posture should be secured in order that the patient may have his only chance of escaping death that is in the most profuse form of hæmoptysis. Even in a hospital for diseases of the chest it is very rarely that a physician is present on such an occasion, for the patient is usually dead within a very few minutes of the onset of such hæmoptysis.

I well remember such a case occurring in a general hospital where I was a resident in 1897. An elderly man came into the casualty room and stated that he had coughed up "half a bucketful of blood." When he expectorated, as requested, into the sputum, the sputum was not even tinged with blood, but he was so blanched that I admitted him. Three nights afterwards, as I entered his ward, I heard a choking cough followed by a splash and splutter. Then came gasping coughs, each followed by blood welling out through the whole width of his mouth. He had sat up in bed, and in a moment he was surrounded by screens and a hypodermic of morphine was injected. The cough ceased, the floor of his mouth fell downwards with rapidly lengthening intervals, but not a guiglo was heard. His eyes became fixed and staring, and within five minutes from the onset the man had been asphyxiated. At the necropsy the lungs and tubes were found to be filled with blood clot.

Unfortunately for cases of this, the severest, type of hæmoptysis, there is an authoritative aphorism that cases of hæmoptysis do not die from "drowning." But if such cases are treated in the way this case was treated they most certainly will be drowned. It may rightly be objected that the patient should have been laid horizontally upon the more diseased side. That would have been better, but, beds being what they are, even the trachea would not have been horizontal. The lower lung would have filled rapidly and the trachea become choked with blood, and it is far more likely that the patient would have fought himself into the sitting posture again.

Contrast that case with the following one. In a hospital for diseases of the chest a fellow resident of mine was sent for to treat a urgent case of hæmoptysis. When he reached the ward the woman was lying on her side, unconscious. The floor of the mouth was moving occasionally, but there was no sound heard to indicate that air was entering the lungs. Obviously this was beyond the routine textbook treatment for severe cases of hæmoptysis—lying on the side, morphine, quiet, and a reassuring smile. Greatly daring, he tried artificial respiration. Still there was no air entry. A week or two before this he had heard of cases of severe hæmoptysis being treated by inversion. He put his arm under the patient's waist and raised her so that the chest was inverted. This also was ineffectual. A nurse changed places with him and he then strongly compressed the chest. A large clot came away followed by some blood, and breathing soon restarted and the patient survived the attack.

In cases of hæmoptysis that are less severe, but still have a copious hæmorrhage, a bronchial drainage posture should be obtained as soon as possible after the onset, and initiated given by inhalation, and some such coagulant as hæmoplastin given hypodermically.

If it is certain which side the blood is coming from, then the old rule that the patient should lie upon the side where there is more disease must be neglected, and, in the bronchial drainage posture, the bleeding side, whether less diseased or not, should be uppermost. It is better that blood should be retained in the more damaged lung than in the sounder one, but it is better still that it should not be retained to any extent in either lung.

The bronchial drainage posture should be adopted in pharyngeal palsies such as that occurring in diphtheria. It may be objected that it is sufficient if the trachea is so tilted that food cannot enter the trachea by gravity. But so often the entry of food into the bronchi has already occurred, and, moreover, efficient coughing may be no longer possible, that the bronchial drainage posture is required for the treatment of pulmonary disease already present or to prevent disease the cause of which is already present.

Where there is paralysis of the diaphragm care must be taken that the abdomen be as far as possible beyond the highest point of the inclined planes, in order to prevent the abdominal contents impeding inspiration by pressing the paralysed diaphragm against the lungs.

Where there is no pharyngeal palsy but merely an inability to cough efficiently the bronchial drainage posture may prove useful, as the following case demonstrates.

A girl suffering from muscular dystrophy had a slight attack of bronchitis and found herself unable to expectorate efficiently. For some days there had been a gradually increasing dyspnoea,

and when I was called in to see her she had already found speaking such an effort that she wrote down everything that she had to say.

She was somewhat cyanosed, the temperature had begun to rise and the respiration was quickened and difficult. Examination of the chest showed a boxy note over the left upper lobe with no breath sounds. Elsewhere in the lungs a few rhonchi were audible and the left base was rather less resonant than the right and breath sounds were weaker. Obviously some tubes had become blocked. Her physician had already tried laying her upon her face, but she was now put upon her right side in the bronchial drainage posture which I have described, but the whole spine and not only the upper dorsal region was placed at the drainage angle. This was done in order to assist in forcing the unparalysed diaphragm into the chest when driving the air out during forced expiration. At first nothing happened. The anterior wall of the abdomen was firmly pressed upon, the muscles being much distended the diaphragm being thereby given a purchase. The patient then took a deep breath, and when she made a sudden expiratory effort I compressed the lower zone of the thorax at the same time. After half a dozen or more similar efforts a small quantity of thin clear phlegm was discharged and two yellow opaque plugs came away. She now became a good colour talked easily and said that she had not felt so comfortable for the last three days. My colleague then found that an entry into the left upper lobe had been restored. We feared that pneumonia might supervene but she was kept in this position for a large part of the time during the following three days, being allowed to sit up or walk about when necessary. At the end of that time the bronchitis had ceased.

This happened some months ago and she is going about as usual. One other point must be mentioned. Owing, I think, to the fact that the pelvis was on the same inclined plane as the thorax instead of upon the other inclined plane as it should be in most cases, the patient had distinct odema of the feet being some hours in the position in which she had been placed.

There is no doubt that the patient would have died had the tubes remained undrained, and seeing that the majority of cases of muscular dystrophy die from pulmonary complications due to the inability to clear the tubes, this method should be found of value in prolonging their lives if it is resorted to early enough.

In a case of acute bulbar palsy due to syphilitic endarteritis and thrombosis, life was prolonged for many hours and far more important in this case, the patient was saved from much discomfort, for he was fully conscious until the heart failed from involvement of the circulatory centre. In a case of bronchitis due to the pressure of an aortic aneurysm the patient was able to get rid of the sputum until an embolism caused a right-sided hemiplegia. He never lost consciousness, but he was then quite unable to cough and expectorate. The bronchial drainage posture was used, and he was able to drain off a considerable quantity of phlegm and was much relieved, although he objected so greatly to his increased helplessness in that position that he was returned to the sitting posture again.

Even had the case been one of cerebral haemorrhage, short spells of the bronchial drainage posture would be justified, because the retention of a continually increasing amount of sputum would certainly cause death, whereas an increase of cerebral haemorrhage and death therefrom, though not unlikely, would not be a certainty.

I have not had any personal experience of postural bronchial drainage in bronchiectasis, but it must be of use in some cases. Something will depend upon the cause of the bronchiectasis and the stage. I remember a case of bronchiectasis confined to the apices, probably due to syphilis, where the drainage must have been efficient during the daytime, but the patient died of indurative disease. Yet the success of surgical drainage in some cases has been great so long as the drainage persisted.

In many cases the patient does not need to remain in this posture for more than an hour or two at a time, if that and the patient may be allowed to rest horizontally for a time, or even to sit up or walk about according to the condition which is being treated.

There is no posture that is perfect in that all parts of the lungs are properly drained in one and the same posture. The posture which I have described drains by far the greater part of the lungs, but one apex may be damaged by maintaining the semi-inverted posture for too long. Whenever it can be done without risk the patient should have a change of posture every now and again into the sitting posture, or at least into a posture sufficiently sloped whereby both apices may be completely drained. I wonder how many cases of hypostatic pneumonia are due rather to weariness of the

power of expectoration than to weariness of the circulation. A patient dying of cerebral disease was placed for thirty-six hours in the right lateral drainage posture, and at the post-mortem examination only pneumonia was present in the right apex—a fact which at least gives a strong hint, although it is but a solitary case.

There must be many conditions similar to those which I have given, where drainage will greatly add to the patient's comfort and there must also be many where drainage is essential if the patient is to recover. There is also a condition where drainage, though of no use to the patient, is a means of sparing others from much distress.

I cannot understand why dying patients are allowed to disturb by the death rattle a whole ward of sick people. Some cases of pneumonia, of uraemia, or miliary tuberculosis, for instance, may continue this ghastly and insistent noise for some hours after it has become obvious to everyone that the case is absolutely hopeless. Were it not hopeless, then maintaining the patient in a posture whereby this noise is made possible is to ensure a fatal termination.

The full drainage posture is usually unnecessary when stopping this noise is the only end in view, and a slight but sufficient change in posture is easily and quickly made. It is a measure scientifically defensible in these cases but there is no doubt whatever that it is, from the point of view of those at the bedside, a humane measure.

SECTION OF OPHTHALMOLOGY.

W. MARION BRAUNTON, M.R.C.S., President

DISCUSSION ON OCULAR PAIN

OPENING PAPER

BY

A. FREILAND FRGUS, M.D., F.R.C.P.S., LL.D.

Consulting Surgeon, Eye Infirmary, Glasgow

I am obliged to the office bearers and committee of this Section for the honour which they have done to me in asking me to open a discussion on the treatment of ocular pain, apart from operative procedure. On two previous occasions I have been asked to open discussions in this Section of the British Medical Association, one of the occasions being at Toronto and the other at Belfast.

May I say that the subject of the present discussion is a little foreign to my usual habits of thought, for I confess that all through my life I have looked at ophthalmology chiefly from the pathological, surgical, and physical sides, and have largely discounted therapeutics in the ordinary acceptance of that word? The reason of that attitude of mind has not been anything rational. Nobody admits more fully than I do the value of many drugs, but after all, the best form of ophthalmic treatment is in my belief, based on pathology, including bacteriology, and on physics. In former days, when I taught students, I always started out with the statement that ophthalmic practice consists in the application of three branches of science to the cure of disease—the three branches being pathology (including bacteriology), physiology (including medicine and neurology), and physics (including, as it does, the study of errors of refraction and of muscular anomalies). I maintain no doubt has rendered some service, but gradually the empirical methods of treatment are giving place, as accurate knowledge increases, to other methods of practice. To the above mentioned it is necessary to add surgery, including modern septic technique.

In great part modern eye treatment should be the application of biological principles to the cure of disease. If I may be permitted to say so, I think that has been the line of greatest progress all through the field of medicine, and from my point of view the great success that has followed the work of public health administration and many improvements in medical work depending upon the discovery of specific micro-organisms are the outcome of biological studies which have had the most far-reaching and beneficial practical results. The important changes which

have been introduced in almost every department of medical work we all acknowledge to have been the outcome of the genius of one man—Joseph Lister. He it was who grasped the significance of the biological researches made by Louis Pasteur and applied his results to the relief of disease. I venture to think that in the history of the human race no other man has done so much as Joseph Lister for the relief of pain and of physical distress arising from disease. There is no need to elaborate a proposition the truth of which is by universal consent cordially admitted. The problem is the same in all departments of the healing art. Major surgical operations do not now almost invariably spell death, people do not perish in the slums of our big towns by hundreds, if not by thousands, from typhus fever and other epidemic diseases, and even tuberculosis is being successfully attacked. All these changes we owe directly to Pasteur's discovery of the action of micro-organic life and to Lister's application of that discovery to surgical practice.

Now I have introduced these preliminaries and, as some may think, trite and unimportant remarks simply for the reason that many ophthalmic problems must be regarded from the point of view that pain is frequently the direct outcome of sepsis.

In discussing the treatment of ocular pain, apart from operative procedure, the first question that must obviously arise is as to the causes of pain. It is only when a thoroughgoing investigation is made of the cause or causes of pain in any particular case does not give a satisfactory and complete answer that the practitioner is justified in taking empirical measures to relieve suffering, although at the same time he may be well aware that he is not getting quit of the disease which is causing the suffering. Roughly speaking, pain in ophthalmic practice is found to depend on two main factors: in the first place, uncorrected errors of refraction, of accommodation, or of muscular balance, in the second place, septic infection. I am at the moment putting all such conditions as acute or chronic glaucoma out of count. In the case of patients suffering from glaucoma the relief of pain depends upon operative procedure. No doubt relief can often temporarily be obtained by the instillation of miotics. My own preference if a miotic is to be used, is for pilocarpine, because its solutions are more stable than those of eserine.

Constant neuralgic pain in or about the eye should invariably lead the practitioner to examine the tension of the eyeball, and if the tension is found to be increased, then the question of operative treatment immediately arises.

As everyone knows, a great deal of ophthalmic pain arises from uncorrected errors of refraction—such as hypermetropia, and astigmatism in its various forms, errors of accommodation are also frequently the cause of a considerable amount of pain which is often attributed to neuralgia. There is only one relief for such a condition of affairs, and that is very accurate correction of errors. Not infrequently patients are found who have been for months, and sometimes for years, undergoing treatment by lotions and ointments, and even drugs, when the only thing wrong was an error of refraction. The corrections in these cases must be very accurate. In some persons a small error of refraction, such as three quarters of a diopter of astigmatism or a diopter of hypermetropia will cause, even in young persons with a fair amount of accommodation, a considerable degree of suffering. Errors should be corrected as accurately as possible. No doubt in corrections a certain percentage of error is inevitable, even when the correction is carefully made, but in a case recently seen the correction prescribed was three quarters of a diopter convex, whereas the patient really had two dioptres spherical and two and a half cylindrical, both convex. An error of over 300 per cent is rather staggering. In all cases when there is pain on reading or when there is pain without any obvious cause the state of the refraction should be most accurately and carefully investigated. So also in middle life, say after 40 years of age, pain occurring on reading where no errors of refraction can be discovered, even on the most accurate investigation, indicates that the function of accommodation should be investigated.

Let us take an example and suppose that the reading distance of an ordinary man is 16 inches from his eyes,

that requires an accommodation equal to about two and a half dioptres. If we measure the range of such a person's accommodation and find that it is only three dioptres, and that his nearest possible point of binocular vision is 13 inches, then he has only a very small reserve of muscular power. A man to read comfortably at 16 inches must have a great deal more than half a dioptre to spare. He must at least have three or four dioptres in reserve. The muscle of accommodation is like every other muscle in the human frame—it cannot keep up a constant strain without very soon becoming fatigued. In many patients the relief of ophthalmic pain will come from ensuring by such a suitable correction that the muscle of accommodation for near-at-hand vision, is not taxed to anything like its full amount.

The other conditions which along with defective range of positive convergence are included under the designation of muscular imbalance are perhaps too numerous and too complicated to come within the range of the present elementary discussion. Fortunately in adequate discussion of them is to be found in many books which are well known to ophthalmic students. Among the early workers in this field of investigation it seems to me that special mention should be made of Alf Graefe, who made a simple test for detecting what he called muscular insufficiency. So far as I am able to form an opinion, the subject seems to have been brought before the notice of ophthalmic workers chiefly by Maddox in the United Kingdom, Landolt in France, and Weeks in the United States. There have been many excellent contributions made by other observers, but these are too numerous to mention.

There is only one form of muscular imbalance about which I should like to say a word. Binocular distant vision necessitates for the maintenance of the parallel direction of the axes of vision a certain exercise of the external recti. Now these muscles cannot be kept at highest tension when they are used for distant binocular vision without getting tired—it is essential that they have a certain reserve of strength—a reserve equivalent to a prism of two and a half or even three degrees minimum deviation. In other words, binocular vision must still be present when a prism of the above noted strength is placed in front of one eye with its edge outwards. A defect in this latent divergence is frequently the cause of a great deal of ocular and peri-ocular pain, and I have reason to believe that it is often overlooked, even by careful and accurate practitioners. I have frequently relieved ocular pain, and that effectively, by diagnosing and treating defective latent divergence either by prisms or by operation. Three in my lifetime I have been able to relieve distress, and that in a very marked degree, by advancing the inferior rectus in cases of impairment of the superior oblique.

The cause of a very large amount of ocular pain is briefly included in the word "sepsis," and hence the necessity for the most careful scrutiny of all the factors which may accompany ocular pain. There are, as we all know, other causes of ocular pain, for example, it often accompanies migraine and is not infrequent in certain forms of peripheral neuritis. With such special forms we have nothing to do at present. Iritis and cyclitis are always septic in origin. When a corneal ulcer or operation wound becomes painful it invariably means that sepsis has supervened.

The ideal treatment consists in the removal of the cause of the sepsis by finding the nidus of infection and dealing with it. That is the proper line of treatment which, if accurately carried out, will ultimately bring relief. Till that occurs, the patient's sufferings must be assuaged by the use of such remedies as may be relied upon to give the needed relief. It is of the first importance to find out the focus or foci from which the infection is derived, and often it is important to identify the germ that is causing the mischief.

It has often appeared to me that from a clinical standpoint inflammatory processes may be divided into two groups. The first of these contains such inflammations as are of mechanical origin. Perhaps one of the best examples of what is meant are the classical experiments of Leber. He put small particles of sterile cinnabar into the anterior chambers of some animals. In each case there were the usual signs of inflammation, but as soon as all the cinnabar

was removed by phagocytosis then the inflammatory symptoms such as edema, congestion at once subsided, leaving, in many cases, permanent changes in some of the structures involved. The characteristics of this form of inflammation are that it is not self-sustaining and does not tend to extend beyond its original locus. Similarly, a wounded surface often heals by a process which many would call essentially inflammatory in character. Of course, a wounded surface may, and as a matter of fact does, very often become the seat of septic infection.

Now in the cases which form the second group the process is entirely different. Here the inflammation is self-sustaining and tends to extension. We now know that the explanation of these characteristics is the presence of bacteria or other organisms which keep up the supply of the irritant, and which also in most instances have the power of extending the site of their operations.

An ordinary wound may cause a fair amount of pain after it is inflicted but that soon passes off and as a rule gives the patient no more uneasiness. In septic conditions the reverse is generally the case, and especially is this true in septic wounds. A patient who has had an operation for cataract suffers a fair amount of pain for some hours after the effect of the local anesthetic has passed off, but after this subsides there is no more severe pain unless something goes wrong. Now the thing that frequently goes wrong is septic infection. Proptosis of the iris, intraocular hemorrhage, and perhaps some other accidents, may cause pain but pain following an ophthalmic operation after the lapse of some hours is almost invariably septic in origin.

Now the infection may come from one of two sources. It may be due to imperfect sterilization of the eye or of the lotions or drops or dressings or instruments or hands of the surgeon or of his assistants. In other words, it may arise from defective technique. It was in 1891 that I began to test the conjunctiva of every patient who was to be submitted to any operation in which the eyeball was to be opened and from that day to this I have not seen retro suppuration follow any such operation. A thorough overhaul, before operation of the conjunctiva of the internal sac of the nasal cavities of the ethmoidal cells, should make a subsequent pyrophthalmitis or pathogenic suppuration absolutely impossible. To my way of thinking the eye is only one safe method of sterilizing the conjunctiva and retrobulbar fold, and that is by saline irrigation. Silver nitrate will only destroy the protecting epithelium and make matters worse. The newer drugs are practically inert. You cannot kill germs in tissues without destroying the tissues themselves. You may, however, be able to remove them by simple irrigation.

But there are other sources of septic infection of an eye which do not so directly depend on faulty technique. Take, for example, an iritis. This is often one of the most painful maladies from which the eye suffers. The pain at times is excruciating. No doubt relief can always be obtained by opiates and by the use of atropine and even by hot applications. But permanent relief is likely only to be secured by the accurate diagnosis of the source of the septic trouble. That source is often in the blood, as in iritis due to syphilis or specific urethral discharge. It often arises from pyorrhoea alveolaris, it is also said sometimes to arise from affections of the intestinal tract. I cannot say that I have been able frequently to associate ordinary acute iritis or cyclitis with tuberculosis, but at the same time it must be remembered that certain chronic forms of cyclitis and iritis are definitely known to be frequently associated with tuberculosis. Most idiopathic, chronic, or subacute inflammations of the uvea are due either to syphilis or to tuberculosis. I do not think there is any reasonable doubt on that matter. Atropine should, if tolerated, always be used in iritis, even when the tension is high. So far as I know it is not germicidal but it breaks up adhesions and seems to be to some extent anesthetic in its properties. It is always the same story if you wish to relieve pain feel out the cause. When you have found it you have, as a rule, discovered the best because the most permanent, method of relieving ocular pain.

Before closing this short introduction to the discussion I should like to mention a subject which has interested me

very much, and that is the application of the biological principles to the treatment of corneal ulceration. That is frequently a very painful affection, but both the ulcer and the pain which accompanies it as a rule readily yield to a definite plan of treatment. I am not at present discussing ulcer with hypopyon nor ulcer with staphylococci either formed or forming, I am dealing only with ordinary ulcers seen in their early stages. In the first place cocaine should never be used, it does not in the least relieve deep pain and has a most disastrous effect on the corneal tissue, atropine is almost equally injurious. When I see a corner with an ulcer and when I find the neighbourhood of the ulcer stony, I know that the ulcer is being treated either with cocaine or atropine or some other mydriatic and is going wrong. On no account should an eye with a corneal ulcer be bandaged. A compress and bandage foment the eye with its own septic secretions.

On the positive side you must promote drainage, and the efficient method of doing that is the moderate use of a miotic, say a few drops of a 1 per cent solution of pilocarpine put into the conjunctival sac once or at most twice daily. The eye should be douched at least thrice daily with sterilized normal saline and may be protected from excessive light by suitable glasses. If this line of treatment be carried out conscientiously when the ulcer is in its early stages, it will be found that no disfiguring leucoma is ever formed nor does hypopyon ever appear. Drainage is essential, and corneal drainage is best promoted by miotics.

When recommending this form of treatment I am sometimes asked as to whether I do not fear the onset of iritis, the answer to that question is in the negative. When corneal ulceration causes an iritis it is because some toxin have got into the anterior chamber, causing irritation of the iris, they can best be got rid of by increasing the drainage by means of a miotic. In other forms of iritis the injurious toxins are not in the anterior chamber, but are in the structure of the iris itself—a totally different state of affairs—and atropine should invariably be used in this latter case.

In conclusion, I have only to say that I hope you are not as much disappointed with my efforts as I am myself. I feel that I have only been tiptoeing over well known ground. It might have been better to have avoided a tolerably wide outlook over the whole field. Had I done so I would have selected the subject of corneal ulceration for review of a fairly extensive practice combined with critical observation of facts leave no doubt in my mind as to the truth of the views above enumerated. If health be given to me for some years longer and if I find the necessary leisure I should like to deal in much greater detail with the subject of corneal ulceration and if I do, perhaps a small corner will be provided for me at some future meeting of the Ophthalmological Section of the British Medical Association. Meantime believe me that my intentions in preparing the communication were of the very best. I find, however, as a general rule of human society that intentions are always better than actual performances, and to that general rule I, as I am only too well aware, form no exception.

GENERAL DISCUSSION

Dr WALLACE HENRY (Leicester) described some instances of reflex pain, and suggested the use of 1 in 4,000 of tetracaine instead of a saline solution for irrigating the eye before operations and when dressing the eye afterwards.

Mr BISHOP HURRY thought there was no one means for the immediate relief of pain in the eye, or, for that matter, anywhere in the body, the application of heat by hot-water bottles, wet hot sponges, and hot fomentations was the most effective method of alleviation.

Mr CARL WILKINSON (Bristol) also advocated the use of heat in the relief of ocular pain. He had found that steam put off from an open rubber bottle placed against the chest and prated with the bottle as is placed against the mouth of an opened eye.

Mr LINDSAY REA (London) reported a case of pain associated with the act of reading or playing an instrument. There was a history of sudden onset of pain while playing, extending over ten years. The patient's refraction was accurately corrected and the muscle balance was perfect. The eyes and conjunctiva were normal, but there was always pain while reading or playing an instrument. In this case the pain must be associated with the various connexions in the brain, "unrepressed pains."

Mr A S PERCIVAL (Newcastle) had found hot sponging almost always successful in relieving pain. He thought dionine was unreliable, sometimes, as for instance in glaucoma before operation, it was very successful in relieving pain, at other times it was of no use. He had been warned against operation on the inferior rectus, and had always been afraid of interfering with this muscle. There were many cases that seemed to be asking for advancement of the inferior rectus for the relief of hyperopia which hitherto he had been reluctant to touch.

Dr L WEBSTER FOX (Philadelphia, USA) said that for the relief of excessive pain he had been using, first, hot water with poppy heads, secondly, hot water with belladonna extract. When atropine irritated the eye dionine was substituted. Last, but not least, leeches were often very useful, also massive doses of salicylates, with injections of 3 to 5 c cm of milk every second day. By increasing the leucocytosis the pain was diminished and the value of medication was enhanced.

Lieut-Colonel A E J LISTER supported very strongly the application of leeches in inflammatory conditions of the eye. They were used very frequently in India, where a man who leapt them applied them for a penny a time. He had never seen them fail to relieve pain in inflammatory conditions of the eye.

Mr FREELAND FERGUS, replying, said that he had no objection to any suitable solution being used for irrigation, but he would be much surprised to find that acriflavine 1 in 4,000 was in any sense germicidal. His own idea in using normal saline was that it was isotonic with the exoplasm, the solution was not germicidal, but it answered the purpose admirably. Whatever might be said about leeches, it was to be remarked that the profession had so far lost faith in them that they had almost ceased to be on sale in Great Britain. As regards dionine, he had seen very severe conjunctivitis follow the application of a 1 per cent solution to the conjunctiva.

THE TREATMENT OF OCULAR SYPHILIS

BY

R LINDSAY REA, M.D., F.R.C.S.,

Ophthalmic Surgeon West End Hospital for Nervous Diseases
and the London Lock Hospitals Assistant Surgeon
Western Ophthalmic Hospital

In the time allotted to me I will endeavour to show the principles guiding the treatment of syphilitic cases which have come under my care. Laboratory methods can help us enormously both in the recognition and treatment of ocular syphilis, but the clinical recognition of the disease in its various and manifold forms is most important. Often when the Wassermann reaction, both of the blood serum and of the cerebro spinal fluid, is negative, one would still diagnose the case as syphilitic.

I lately have had help from Lange's colloidal gold reaction. Although the luetic curve is similar to that of disseminated sclerosis, yet it is of great value in establishing the diagnosis of syphilis, as in a case of retino-choroiditis when the Wassermann reaction both of the blood serum and of the cerebro spinal fluid, was negative, but the colloidal gold test showed this curve. Vision was diminishing, but treatment with mercury and iodides arrested the disease, and vision rose from 6/24 to 6/6 in one eye. Unfortunately the macula of the other eye was involved, and the vision of that eye remained poor.

Lately P H Jones published in the *BRITISH MEDICAL JOURNAL* (May 2nd, p 821) a paper entitled "The effect of antisyphilitic treatment as gauged by the Sigma reaction." This reaction was introduced by Dieyer and Waid, and was an attempt to establish a quantitative test which would show the effect of treatment by the fall of "units" in the blood test. In this paper, regarding tertiary syphilis, Jones says "In the majority of cases, however, the units can be reduced, but eventually take up a new level which is uninfluenced by treatment." Reading this we might be led to suppose that the treatment of tertiary cases is often ineffectual, although I do not think Jones meant to imply this, and clinical experience shows that if a tertiary manifestation is attacked at once by antisyphilitic treatment, which includes intravenous treatment by novarsenobillon, there is a splendid response. A gumma of the conjunctiva, which at first resembled an ordinary phlyctenula but resisted all treatment until its real nature was discovered, resolved completely in a short time under treatment by novarsenobillon. In another case a gummatous infiltration of the orbits included the left antium and ethmoidal region. The left eye was rapidly becoming markedly proptosed and fixed the lids would not meet over the corner, the right eye began to come forward also, while the left eye became completely blind. The Wassermann reaction of the blood serum was strongly positive. At once 0.45 gram of novarsenobillon was given every fifth day for eight weeks together withunctions of mercury into the abdominal wall and temples, with 15 grains of potassium iodide three daily. At the end of three months, mercury and iodides being used daily, the eyes had returned to their natural positions, movement had returned, and the vision of each eye became 6/6 as formerly.

Although Jones found that 0.9 gram was the most effective dose of novarsenobillon for lowering the unitage, yet it is my clinical experience that doses such as 0.45 gram rapidly repeated are more effective than 0.9 gram doses given over a longer interval.

One observation I have made, and in this Dr Ravner Batten agrees with me. I have never seen disease of the macula due to syphilis. True, the macula is often found affected by the disease, but evidences of the disease are also found elsewhere in the retina, in one such case the macular involvement was but a coincidence in the retinitis. Also I have seen evidence of arterial disease around and affecting the macula in a patient suffering from a generalized obliterative endarteritis, but again this was not a macula disease *per se*.

What is really the value of arsenical preparations such as novarsenobillon, and do they offer any advantage over mercury and iodides? Macintosh showed that cases of syphilis treated by mercury and iodides at the end of a year showed a negative Wassermann reaction in 92 per cent, at the end of the second year 54 per cent, and at the end of the third year 30 per cent. Arsenical preparations give us a much more rapid result, and save the eye from the damage which would ensue from prolonged exposure to the syphilitic virus. I have come to the conclusion that novarsenobillon gives the best result.

A question which presents itself rather frequently is that of the duration of opaqueness of the vitreous body when the retina or choroid body is attacked by syphilis. Although the vitreous body may remain opaque for over two years, I have seen it clear up, allowing the fundus to be clearly seen. In one of the cases mentioned by Sir William Lister at the Washington Congress last year the vitreous became clear, but a ring "hole in the hyaloid" was found fixed and situated in front of the optic disc. Apparently as a result of the disease, the vitreous became detached from the region of the optic disc, the lymph sheath becoming thickened and visible and showing as above mentioned. In these cases the vitreous may show local cloudiness, and it is this in the region of the optic disc a blurred effect is produced, but care should be taken not to diagnose the case as one of papilloedema. The extremely fine changes in the retina may be found by carefully searching as far forward as possible in the region of the equator.

The treatment of cases due to congenital syphilis is very efficiently carried out by novarsenobillon. It has been a source of confusion in the minds of many ophthalmic

surgeons that, no matter how many intravenous injections of any arsenical preparation are given, the Wassermann reaction will not become negative. In the majority of cases this is true, and yet whether treatment is given or not Nature will eventually produce a negative reaction. A patient, aged 29, presented himself to me with a marked scleritis in one eye. A Wassermann test was negative. This patient had interstitial keratitis when 10 years of age, but had never received antisyphilitic treatment. Another case, a woman of 49, who when 24 years of age suffered from interstitial keratitis in both eyes, now has just recovered from an attack of nits which yielded to a series of injections of novarsenobillon. The Wassermann reaction was strongly positive, although the patient had not run the slightest risk of infection. It is evident, therefore, that in acquired syphilis the Wassermann reaction can indicate the result of treatment, but in congenital cases it is the clinical manifestations which must be observed of the measure of thorough treatment.

In my little book on the treatment of interstitial keratitis I have published three tables. The first shows a number of cases which never had antisyphilitic treatment, and the common result is greatly lowered vision—some eyes were blind, while some had chorioiditis or staphylomata; these cases showed deafness in more or less degree. The second table records those cases which had not received treatment for some months after the onset of the disease. The results shown are similar to the previous table, but Table III shows the result of prompt antisyphilitic treatment in 63 cases which I was able to treat myself from the onset of the disease. In this series there is not one result comparable to any of those shown in Tables I and II, and, further, I did not find a single case showing the onset of deafness. I have come to the conclusion that if the majority of cases of ocular syphilis are treated vigorously with such preparations as novarsenobillon the results, although not dramatic in suddenness, are consistently good.

It must always be remembered that in inflammatory conditions of the eye produced by syphilis, atropine in the form of ointment must always be used. This will prevent adhesions forming in the pupillary margins, and keeps the iris at rest.

DISCUSSION

Mr BISHOP HARMAN (London) said that he was curious about one statement made by Mr REX—namely, that the test of efficient treatment of ocular disease in congenital syphilis was the prevention of the onset of deafness, which seemed to imply that deafness was general in blind syphilitic children. In his experience that was not so, amongst the children in schools for the blind, blind and deaf children were in a very small minority indeed. In his own view the one successful mode of treatment of ocular syphilis in children was by prevention through the efficient intra-uterine treatment of the parents before conception took place or as soon after that event as possible. Such methods would save endless labour from doctors, educationists, and social workers, and a lifetime of misery in the case of the sufferers.

Dr D J PRINROSE (Glasgow), in a large experience in Glasgow Eye Infirmary, had found very great and immediate benefit from the prompt use of the newer treatment by injections. Children as a whole stood treatment by mercury and by arsenic very well indeed, and many were able to have both, though not all. Where only one could be tolerated it was well to choose the more efficient and prompt in its action, the salvarsan substitutes. It was important not to neglect the other measures well known to ophthalmic surgeons where necessary atropine, blisters, rest in bed in acute cases, should be employed, also general hygienic measures, and—most important in large cities—change of air to the country.

Lieut.-Colonel A D J LISTER, I.M.S. (ret), congratulated Mr Lindsay Rex on his paper. There was much difference of opinion in ophthalmic literature as to the value of these arsenical compounds, but his own experience

had been that certain cases which had not been doing well on ordinary methods had responded to injections of these compounds administered by an expert. They had in some cases done very much better than his experience would have led him to expect from the older methods, of which he had had an extensive experience.

Mr CROFT B T TAY (Plymouth), while a firm believer in the treatment of interstitial keratitis by organic arsenical compounds, was frequently called upon by colleagues to justify his belief. He regretted that the paper just read had not left him with an absolute answer. He had made a habit of giving thyroid extract in suitable doses, and had noticed benefit.

Mr LINDSAY REX, replying to Mr Bishop Harman, said he had not meant to imply that every case of interstitial keratitis would become deaf, but Hutchinson and Jackson had said that deafness most generally supervened when the interstitial keratitis was passing off. They could not afford to take risks, and must therefore treat each patient thoroughly. Replying to Mr TAY, the average time taken for the cornea to become clear was from six to eight months. Even if there was a recurrence treatment must be continued, perhaps for as long as two years. Thyroid extract would not cure syphilis, though it might produce alterations in the tissues. If novarsenobillon could not be given, then 6 eg sulfarsenol could be injected into the buttock weekly.

THE CONSERVATIVE TREATMENT OF GLAUCOMA

J BURDON-COOPER, M.D., F.R.C.S., B.Sc., D.O. Oxon.,
Senior Surgeon, Bath Eye Infirmary

My justification for inflicting this paper upon you lies in the desire to bring to your notice the value of the combined use of morphine and nitroglycerin in cutting short an attack of congestive glaucoma. I wish also to make a suggestion whether, in view of the present state of the glaucoma problem, the time is not now ripe for us seriously to consider the development of a well thought-out stereotyped method of conservative treatment, applicable to the disease in all its forms, and if this were done, whether the treatment of the disease as a whole might not thereby be further advanced.

I think all will be agreed that the highly technical character of the operations we are now called upon to perform, in which the greatest accuracy is absolutely essential to success, demands at least as suitable a condition of the eyes and the patient beforehand as it is possible to secure, and herein lies the value of conservative treatment. This suggestion, I wish to make clear, offers no plea for the non-operative treatment of glaucoma, but rather the reverse, as I personally am convinced, speaking generally, that early operation in all forms offers the best results ultimately. My plea is that well thought-out conservative treatment should be supplemental to and not divorced from the operative.

While we recognize that no treatment is of much value which is not based on a correct etiology, the disconcerting fact is, as another has said, "while we are seeking to unravel the cause, the patient becomes blind." Operation, therefore, becomes essential for the relief of the symptom—namely, the tension, but this is no excuse that the etiology and pathogenesis of the disease should receive no consideration. It is in direct relation to this that conservative treatment is of such value.

The scope of such treatment is very wide. All we have to do to see this is to review the associations of glaucoma with which we are acquainted. There is not time in such a paper as this to consider the problem fully; still, I would like to refer to some of the associations which have especially struck me as important, and first I should place the nervous system. The influence of irritability and worry is well known. One of the most remarkable cases of glaucoma I ever saw was in a woman of 23, whose double glaucoma came on as the result of the depression and worry due to the breaking off of her engagement. It was kept in abeyance

CONSERVATIVE TREATMENT OF GLAUCOMA

for some time by miotics, but rise of tension and haloes came on whenever she got depressed and down, and especially when she heard prismatic music. These became so numerous and the visual acuity and fields so reduced that eventually, about a year after I first saw her, I had both eyes to triphine.

The question of arterio-sclerosis and blood pressure is one that opens up a wide field. Local arterio-sclerosis has been proved to exist in glaucoma. On the question of blood pressure, some opinions seem to differ, some authorities maintaining that there is no direct connexion between raised blood pressure and glaucoma, others that glaucoma without raised blood pressure, though certainly met with, is rare and gives rise to suspicions of its primary origin. My own observations lead me to think that an attack of congestive glaucoma is rarely precipitated without a temporary rise in the systolic pressure.

I have seen an attack of congestive glaucoma begin with a rise of 20 mm. of mercury above the average blood pressure for that individual, the record of which had been taken for weeks. Glaucoma has well marked associations with inborn errors of metabolism, and it is of capital importance to seek for and remedy metabolic disorders. Primarily glaucoma is associated with hepatic insufficiency, relative renal impermeability, diminution in the destruction of albumin within the body, intestinal troubles, chronic instability, and arthritis. If to any of these is added a local ocular predisposition all the factors are present for the development of the attack. A variation in the tension between the two eyes has been noticed with distal metabolic disorders. Gout, rheumatism, and the relative acidosis associated therewith, have been often noticed as concomitants of glaucoma.

Fisher went so far as to say that the swelling of the coloids of the eye (due to acidosis) might be the cause of glaucoma, the swelling leading to pressure and constriction of the blood vessels, venous stasis, and deoxygenation of the blood. Relative acidosis, as far as my experience goes, is an important factor in eye disease as a whole, glaucoma included, and every effort should be made to discover the factors responsible for it. Diet too, is of importance in helping them food and the molecular concentration of the blood. This change he thought, was independent of the blood pressure and could only be due to osmotic processes. The drop in intraocular tension in the coma of diabetes is probably of this nature. The influence of acute disease is well recognized. In secondary glaucoma syphilis should be borne in mind, thus helping the iridocyclitis and chorio-retinitis associated with it.

Thus briefly reviewed, are the avenues in which our energies in connexion with the conservative treatment of glaucoma may find their scope. I now proceed to deal with that which is my immediate subject—namely, the value of morphine and nitroglycerin.

As I have said before it is impossible for me to deal with all the forms of glaucoma, and that which is mainly acute is the congestive attack. These attacks usually come on for the first time in the course of a debilitating illness such as influenza, either during or after it, my last three cases in the spring of this year were of this nature. It may also be stimulated, in eyes which already have glaucoma, simply, by indiscretion of diet some excitement, or prolonged use of the eyes.

An interesting case I saw many years ago commenced in this way. An extremely sudden attack occurred in the case of a miniature painter after using the eyes it might be said for some hours and I had the good fortune to see it a quarter of an hour after it began. The eye then was quite white and free from congestion with a three quarter dilatation of the pupil but it was as hard as a stone, and the patient was nothing in a way in bed vomiting and comatose. It is the only case I have ever seen of acute glaucoma early enough to show no congestion. I used morphine and continuous dry heat—I was not aware then of the value of nitroglycerin. The eye was undisturbed for ten hours after the onset of the attack and did well, though the vision previously had been reduced to hand movements.

It is the class of case that the general practitioner invariably sees first, and with a good conservative treatment he can render great help. Even supposing the case comes directly into the hands of the ophthalmic surgeon, if controlled by treatment an operation can be performed with much greater precision with the eye quiet. Given such a case, how are we to proceed?

My method is to give a bath to commence with. With regard to the bath, it is important that it should not be too hot, as if so the peripheral vessels are contracted and not dilated. What is wanted is the dilatation of the peripheral vessels, and this is best secured by a bath at a temperature about 50 above that of the body. The object is to relieve the internal congestion by peripheral dilatation of the blood vessels, this is essential. After the bath, when the patient has been put to bed I give a hypodermic injection of 1/4 grain morphine and after this an alkaline mixture containing bicarbonate and citrate of potash and soda, with one minim of liquor tinitini for a dose every three hours. The skin should then be encouraged to act by a pack with uniform continuous warmth obtained either by a pack with uniform con-packing with hot bottles.

It is wise to have the urine tested beforehand the only contrary indication to the continuance of the nitroglycerin is the heart's action. I never like the pulse rate to exceed 90, should the medicine need to be prolonged, as in case of secondarily glaucoma with irido-cyclitis. The hypodermic of morphine should be repeated the last thing at night and kept up twice daily until the attack begins to decline. Neither drug acts so well alone, and I think the good effect is due largely to the relaxation of the peripheral circulation and consequent reduction in the blood pressure.

In a case I recently had under my care the patient objected to the morphine when she began to improve, and I omitted it for once, with the result that the tension crept up again. It is better not to interrupt the treatment at first and to keep it up certainly for two full days or more. The continuous application of dry heat to the eye, applied by means of Dr. Maddox's eye warmers, is, I think, essential, and is a very valuable measure in helping to reduce both the ocular tension and pain. The pads should be kept on continuously and the patient may even sleep with them, they should only be removed for a time, as a little relief, till the eye shows manifest signs of improving.

Ocular hypertension can in a large measure be controlled by heat, the heat, together with the morphine and the soothing influence of the nitroglycerin, relieves the pain and helps the patient to sleep, which is the natural cure for glaucoma. I always use cocaine for an acute attack, and preferably the salicylate in 1/2 per cent solution, which is instilled into the eye every three hours. I prefer an aqueous solution and not an oily one, as I think it is absorbed quicker. Directly the attack subsides the drop should be changed to pilocarpine 2 grains to the ounce, which should gradually be reduced to 1 grain or even half a grain. The rule for miotics is to use drops infrequently and as weak as possible, compatible with securing the necessary miosis. The irritation they give rise to can be readily met by washing with any bland solution such as simple boracic lotion between the instillations, and often with greatest comfort to the patient.

While on the question of drops, I would like to mention that I do not consider that either thionine or adrenaline should be used. In any case, the former is only used for its analgesic effect, which can be readily met by heat and the latter is dangerous. It may on account of its action in stimulating the dilator pupillae dilate the pupil and raise the tension. I have used an injection of adrenaline in two cases, according to the method of Hamburger, but I must say that I have not been impressed with it. In one case the patient an old man became so blanched generally and his pulse so slow that I thought he was going to collapse. Nothing in the nature of a tonic should have been given to the patient beforehand, especially now which is a dangerous drug to give in glaucoma.

As regards subconjunctival injections I have never given them. The Harbison test in that may be tried where mine has failed to reduce the tension and has its great effect in early glaucoma.

them in glaucoma, as such injections cannot be carried out without some pain, however much we try to prevent this, to aggravate this pain, with the patient suffering enough, and for a doubtful advantage, has never appealed to me. Sodium citrate in 4 to 5 per cent solution has been used, and is said to produce a fall in the tension as much as 10 mm of mercury after injection, which reduction is said to last from three to six days. It is thought to act by diminishing the swelling of the vitreous. The most recent work has shown that these injections do not reduce the tension at all some have even been known to raise it, where it fell, the fall was less than that given by eserine. Injection of the nasal duct with 25 per cent atropine and scrubbing the nasal fossa with 50 per cent cocaine over the region of Meckel's ganglion has been advocated for the relief of pain. The pressure massage of Domec is very useful and should be frequently done, I usually massage my private patients every two hours for a few minutes at a time, with antero-posterior pressings of the eye through the lid with the thumb on the globe and fingers of both hands on the temples to steady them. A firm vibratory motion is better than a severe punch. Knapp estimated that he could reduce the pressure 8 to 10 mm of mercury by a thousand pressings, the amount I have found is, on the average of a dozen cases, 6 mm of mercury for the unoperated eye, and 10 mm for a sclerectomized eye. Vibrations kept up for five minutes show more reductions in the sclerectomized than in unoperated eyes, as the curves show.

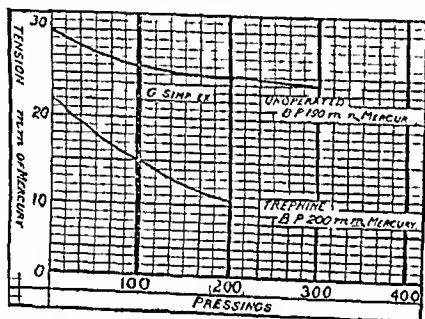

Chart showing reduction in tension by massage in unoperated and trephined eyes both subject to glaucoma

Venesection in glaucoma has been in my hands a useful measure in combating an acute attack, it can be employed according to the method of Dyes—that is, removing 3 gms of blood per kilogram of the body weight of the patient from, say, the median basilic vein, it always diminishes ocular tension in glaucoma simplex in six to eight hours and in inflammatory glaucoma in twenty-four to forty-eight. I have never pushed it so far as actually to reduce the blood pressure as indicated by the sphygmomanometer, though I think this is worth trying in a case which is not yielding readily.

In established glaucoma venesection should always be performed. I have been greatly struck by the effect of simple scarification of the temple and the abstraction of one-half to two ounces of blood by means of Bier's suction tubes or an artificial leech. In a definite case of secondary glaucoma I treated four months ago it had a marked effect, and I consider was the measure which determined the quietening of the eye. The patient had both morphine and nitroglycerin. Curiously enough I found the temple to be the best place and not the mastoid, I do not think it is the quantity of the blood withdrawn that is so important as the reflex effect it has upon the nervous system, but this point needs further investigation.

Coming now to the general care of the patient, perfect rest and quiet are essential and the room should be only partially lighted. It is important to have the air of the room moist, and I always use a bronchitis nettle, the influence of atmospheric humidity on eye inflammations was forcibly brought to my notice many years ago. I had been asked to look after a patient with post-operative eyeitis and no treatment I applied did any good whatever suddenly, without any further effort on my part, the eye

got much better, and on seeking a cause for this I noticed that the improvement coincided with a thaw which had set in after a long bout of black frost and a high barometer. I have since amply confirmed this observation on humidity and in no part of our work more so than in glaucoma. Cold dry air and high barometric pressure are bad for glaucoma cases.

Inhalation of oxygen has been recommended to me, but so far I have never tried it. It certainly would relieve the heart and improve the deoxygenation of the local blood supply consequent on the stasis.

As regards the general condition, the diet should be restricted and non-stimulating, and during the height of the attack large quantities of fluid should be prohibited. After the tension has come down the kidneys may be stimulated. A good saline purgative at the commencement of the treatment is helpful, though I prefer in private case to make little alteration in the medicines the patient has been habitually taking. Among the drugs I have found most useful are the alkalies, iodides, salicylates, sodium bromide, chloral hydrate, strophanthus, andgelsemium. The latter is especially valuable for alleviating the irritability and relieving both headache and pain in the eye. Lithiol tetrahydrate was recommended to me in place of nitroglycerin, but the only case in which I tried it did not do well at all, and I had to go back to the nitroglycerin. I have never tried any substitute for morphine.

In avoiding subsequent attacks it is advisable for the patient to lead a quiet life, free from anxiety and worry, chills should be avoided and woollen clothing should be worn next the skin. Special attention should be given to the lungs, heart, intestine, nasal sinuses, and the teeth. One or two things have especially struck me in connection with the care of the patients after such an attack, and the first is the climate he should reside in. The question of climate was first brought to my notice in treating a case in of the late Mr. Nettleship whom he put under my care. She had glaucoma simplex, and iridectomy was performed in both eyes. The only way we could keep her eyes comfortable was to give her nitroglycerin as medicine when she lived at home on Combe Down, one of the higher parts of Bath, failing this, she had to winter lower down, and later in the South of France. The climatic treatment of glaucoma is important. In my opinion high altitude and too bracing and dry a climate is bad, and although I know glaucoma patients see better in such places, my contention is that they are much safer from the risk of acute attacks at the lower altitude and in a more humid climate. Secondly, general medical care between the attacks is also of the greatest value in reducing their frequency. I have before me a case which I have followed since 1905, when the patient had iridectomy performed for glaucoma simplex. Since then till 1913 she has had four attacks of congestion—that is, about one every two years—and the average period of treatment was thirty-three days. Since 1913, when I began more detailed treatment and advised wintering abroad, she has only had two attacks—that is, one every five and a half years—and my average time of treatment for these was seven days.

DISCUSSION

Dr. CHALMERS JAMFSON (Brooklyn, U.S.A.) expressed pleasure in hearing Mr. Burdon-Cooper's lucid and comprehensive paper. Often the surgeon's attention was concentrated upon the operation and the general and specific conditions to which Mr. Burdon-Cooper had alluded were neglected. He was glad Mr. Burdon-Cooper advocated the early operation in simple glaucoma. This corresponded with Dr. Jamfson's own feelings, and his histories showed that patients treated with miotics alone

nearly always played a losing game. In cases in which one eye was iridectomized the operated eye always held the fort for the longer time. Dr Jameson desired to advocate what might be considered a very unconservative procedure, to be used, however, in a conservative way, at least for the present. He had recently tried some posterior trephining in the region of the equator. These operations were performed on the premiss that if the venae vorticosae (by reason of their oblique passage through the sclera) were shut off and strangulated, and that if the suprachoroidal space by pressure was in part obliterated, a trephine in this region might restore the pituitous quality of the venae vorticosae, and re-establish the space. This, if successful, would mean the restoration of the return circulation, the larger part of which returned through the venae vorticosae, and also pressure relief to the incoming circulation and nervous supply, both of which passed through the suprachoroidal space, the lymph flow through this space communicating with the ciliary lymph channels was re-established. This procedure met with much success. All the eyes (five in number) were blind, of excessively high tension, painful, and subjects for enucleation. They had all been saved, to his knowledge, except in the case of one patient who precipitately left the hospital and the result was not known. The first, with the excessively high tension of 150 degrees, after a double trephine fell to 30 degrees, and this had been maintained for six months. In one case perforation had occurred, and this was the danger, although in the blind painful eye the chance could be taken. In eyes of lesser tension this danger would be greatly reduced. The subject of posterior trephining in this region undoubtedly opened a field for investigation, and could now be adopted as a conservative procedure in blind eyes where, by reason of pathological block or possible haemorrhage from friable tissue opening of the chamber was contraindicated. Dr Jameson hoped to operate by this method on eyes of lesser tension where the field of vision was considerably reduced.

SOME THINGS I DO NOT KNOW

BY

A. S. PERCIVAL, M.A., M.B.,

Senior Surgeon, Northumberland and Durham Eye Infirmary

Tobacco Amblyopia and Chronic Retrobulbar Neuritis

How can one distinguish a chronic double retrobulbar neuritis from what is now called toxic amblyopia? They both present very similar symptoms and no objective distinctive signs. In both there is a central colour scotoma, especially for green and red, and a general diminution of central vision. In both, after resting the eyes for one or two minutes by closing the eyelids, the sight is better, but presently floating clouds of fog obscure all details. In both sight is better in a dim light, and the light difference suffers more than the light minimum. Dr Schweinitz apparently makes no distinction between them, at any rate, he treats them both under chronic retrobulbar neuritis, with tobacco amblyopia in parentheses.

Those who have worked at the pathology of the condition found in tobacco amblyopia have given very different accounts of what they have seen. Samelsohn, Nettleship, and Vossius regard it as a grey degeneration of the axial part of the optic nerve, apparently starting from the region of the optic foramen. Of course we all know that the macular fibres at the site of the optic foramen occupy the axial part of the optic nerve. Noel regards it as essentially a disease of the macula itself. Langley has taught us all that tobacco paralyzes the ganglion cells, so it may quite probably be due to a primary change in the ganglion cells of the retina in connexion with the macular and perimacular nerve fibres. But it is exceedingly difficult to get specimens of pure definite tobacco amblyopia for examination. Nettleship's case was that of a diabetic who had smoked excessively, the case of Vossius was that of an alcoholic, here in Great Britain we almost all attribute the cause to tobacco in America and elsewhere abroad more stress is laid on alcohol, or alcohol associated with tobacco. Of course, it is easy to say that practically all who smoke

drink also, but I have seen one typical case in a teetotaler who said that he smoked 2½ oz of brown twist in a week, and who recovered completely on leaving off tobacco, taking a strychnine mixture, and eating as much watercress as he could.

I have been in the habit of ordering watercress in tobacco amblyopia since reading in *La Semaine Médicale* (March 22nd, 1905) what a perfect antidote Zalkowich found it to be to lethal doses (0.025 mg.) of nicotine in rabbits, and subsequently in dogs. I think there was some earlier work done on the same subject by some French experimenters on guinea-pigs, but I have been unable to find the reference. The expressed juice of watercress was given by injection into the veins. Incidentally I may say that in every case but one that I have seen the tobacco used was shag in the South, and brown twist in the North, and that the amount used was not excessive, very rarely exceeding 2½ oz a week. I imagine that those who are predisposed to tobacco amblyopia have already found that tobacco does not altogether agree with them, and therefore they are moderate in the use of it. I have been quite unable to discover any adulterant common to shag and brown twist which would explain the liability to induce amblyopia.

I personally object to the term "toxic", we know of toxic amblyopias due to sodium salicylate, to opium, to uranium, which may all completely recover, and to quinine, diabetics, lead, etc., in which the prognosis is not so favourable. I have never seen a case of wood-alcohol poisoning, which is so prevalent in America and gives rise to optic atrophy. But surely the pathology of these conditions is not the same. It is incumbent on us to recognize clearly what we do not know, and not to conceal our ignorance by using a general term like "toxic," which may include half a dozen different pathological conditions. I would urge you all to lose no opportunity of getting the eyes and nerves examined by a pathologist in every case of amblyopia or amaurosis when possible. I hope you will have better luck than I have had.

We all talk glibly enough of an ascending degeneration in retinitis pigmentosa, for instance, and of a descending degeneration in cases of prolonged pressure on the optic nerve or chiasma, but I do not think that any microscopist can say from the examination of the slide of an optic nerve (which has no nodes of Ranvier) to which class the case belongs. The observations of Samelsohn, Vossius, and Nettleship, even if they were all cases of tobacco amblyopia, might be due to an ascending degeneration.

Paralysis or Paralysis of Accommodation

Are all cases of paralysis of accommodation subsequent to a history of some throat diphtheritic in origin? For some unknown reason I have seen far fewer of these cases during the last ten years. They generally seemed to occur after a follicular tonsillitis, occasionally there was also a paralysis of the levator palati, when I was inclined to think that the case was diphtheritic. Generally there was no history pointing to diphtheria, no paralysis of the soft palate. Some of you will say that a scrub from the throat would clear up the matter at once, but would it?

Apart from the difficulty of distinguishing the Loeffler bacillus from the apparently innocent Hoffmann's bacillus, I gather from Professor Hatcher's translation of Besson's *Bacteriology* that "less than half the number of individuals in whom the bacillus obtains a lodgement are attacked by the disease." Again there is no valid reason to expect that during a late diphtheritic neuritis Loeffler bacilli should always be obtained in the throat. I am no bacteriologist, but I fancy some of us lay too much stress on bacteriological reports, I hasten to add that perhaps most of us, including myself, do not call in their help often enough.

Ciliary Injection with Glaucoma or Iritis (Tonometer)?

There may be an increased tonometric reading in either, but we have all encountered this stock question in one of our professional examinations, and we have found that most examiners are content if we give the very unsatisfactory answer that reliance, or at any rate great weight, should be placed on the size of the pupil. But in practice

we are rarely the first to treat the patient and the pupil is already under the influence of a motie or a mydriatic. Surely stress should rather be laid on minute examination of the iris with a loupe, notis can, I think be always detected by this means, but most important of all is the examination of the nasal field of vision and of that near the blind spot.

But you will say that in the last paragraph I have only been saying what I think I know, not what I do not know. But with me a moment. I spoke of an increased tonometric reading. I used this term because I do not know what it means.

In medicine generally an appalling ignorance of elementary physics is shown, we hear of blood pressure and uterine tension, of ocular pressure and ocular tension, as if they were synonymous expressions. Tension means a pull, and pressure means a push, as our master Priestley Smith sums up the matter. The tonometer gives the weight that will dimple or flatten the convex surface of the cornea. This depends upon the rigidity of the cornea, upon its curvature, and upon its size and the size of the globe, as well as upon the chamber pressure. Thus the internal pressure on the sclera and on the cornea is the same, but the tonometric reading is different. The internal pressure per square millimetre is the same in an aneurysmal sac and in the artery that feeds it, but the aneurysmal sac is the more stretched, is more tense, and consequently bursts, and would burst if stretched enough quite apart from any disease in its wall. The greater the curvature of the surface the more easily is it dimpled by the finger. Rayner Batten and later Priestley Smith have shown us this in a very simple and striking way, indeed, I have been quoting from this paper in the last ten lines. Further, the size and shape of the foot of the tonometer make a very great difference in the reading of the instrument. For all these reasons I personally distrust the value of any single reading with a tonometer. A series of readings made by the same observer with the same instrument on the same patient is invaluable in showing the progress of the case, but one observation which takes no account of the individual peculiarities of the eye may be most misleading.

The Chart of a Central Scotoma

I do not know if it has any value. I see apparently most accurate charts published of central scotomata in different conditions, but how on earth can a chart be taken when the eye examined cannot fix its gaze definitely upon one point? One patient I saw three times in one week, on each day I took two charts—no one of the charts resembled another. The poor man could not keep his eye fixed in the same direction. I have tried fixing the sound eye in one case of monocular central scotoma, but I obtained discordant results with even this. I never attempt to take a chart of a central scotoma now—it seems to me pure waste of time. If anyone here can tell me how a central scotoma can be accurately traced I shall be exceedingly grateful, but until I learn how it can be done I shall continue to have the most profound distrust of all such charts.

DISCUSSION

Mr W B INGLIS POLLOCK (Glasgow) said that the most recent work on perimetry pointed strongly to the retinal origin of tobacco blindness, and the older pathology of fifty years ago was not quite reliable on nerve poisons.

Dr PETER MACDONALD (Lith) agreed that tobacco amblyopia was usually due to such tobacco as shag and twist, but gave an account of an undoubted case of tobacco amblyopia due to cigarette smoking only.

Dr J W TUDOR THOMAS (Cardiff), referring to paralysis of accommodation, described a case in a young man. There was no affection of the throat, and the only point of interest in the history was that he had sustained an ulcer of the little toe through wearing new football boots,

to which no especial significance was attached. The appearance of further symptoms led to bacteriological examination of the ulcer, which proved to be diphtheritic. Appropriate treatment cured the paralysis of accommodation to disappear.

PSUEDO-GLIOMA

Mr A S PERCIVAL (Newcastle-upon-Tyne) showed a glutinous specimen of pseudo glioma in a child, aged 2, who was said to be recovering from meningitis. When he saw her she had left pseudo glioma and right retrobulbar neuritis from which she made a partial recovery, her sight improved considerably. The specimen showed detachment of the anterior layer of the choroid and the retina by an effusion. The dense black pigment in front was probably due to blood. The vitreous was represented by the greyish material behind the lens. The specimen had been previously exhibited at the Convention of English speaking Ophthalmologists. Mr Percival urged the importance of searching for symptoms of retrobulbar neuritis where choked disc was anticipated but not found. In one case of cerebral tumour he found symptoms of retrobulbar neuritis (verified *post mortem*) and no choked disc.

Mr Percival described experiments which appeared to indicate that pseudo glioma, retrobulbar neuritis, and choked disc might all arise from the same condition.

On injecting the sheath of the optic nerve in the *post-mortem* room he had made the following observations:

1 In children under 5 the fluid under the sheath travelled directly to the lymphatic spaces in the choroid detaching the anterior layer of the choroid and the retina from the posterior layer of the choroid and the sclerotic. This was the condition in pseudo glioma.

2 In one adult he had found that the fluid met with a block at the site of the optic foramen, the bulging sheath being constricted beyond this point. This was the condition presumably in retrobulbar neuritis.

3 In all other adults the fluid met with a block at the sclerical opening. This was the condition in choked disc.

Clearly the dura was continuous with the sclerotic, the uvea and par with the choroid, and the nerve fibres with the retina. It was he believed, recognized that optic neuritis did not occur in dogs. In the only two dogs on which he tried this experiment, condition 2 was observed, probably in dogs retrobulbar neuritis always implied choked disc in men.

COMPARISON OF THE NARCOTIC EFFECTS OF THE TWO HYOSCINES (SCOPOLAMINES)

BY

J CHASSAR MOIR, M B, CH B

(From the Pharmacological Laboratory University of Edinburgh, and Royal Simpson Maternity Hospital Edinburgh)

Hyoscyne exists in two forms, which are identical in their reaction to ordinary chemical reagents but differ in the direction in which they rotate the plane of polarized light, and are therefore known as optical isomers. The levo-rotatory alkaloid is that occurring in nature and used in therapeutics, the dextro-rotatory may be formed artificially from it. A mixture in equal parts of the two isomers, known as racemic hyoscyne, is not infrequently met with, especially in old solutions of the natural form. While these forms cannot be differentiated by ordinary reagents, they can be distinguished by substances which themselves rotate the plane of polarized light and are optically active. In a number of instances similar isomeric substances have been shown to differ in effects on living tissues, for example, the natural levo-rotatory hyoscyamine and adrenaline are some fifteen to twenty times as powerful as the dextro-rotatory hyoscyamine and adrenaline. It was therefore of importance to determine whether a similar difference existed in the two hyoscines. As regards their action on the peripheral nerve, the racemic form, containing equal amounts of dextro and levo-rotatory hyoscyne, was found to be only one half as powerful as

the laevo rotatory,¹ and later experiments gave the activity of the laevo-rotatory is from sixteen to eighteen times that of the dextro-rotatory one. In animal experiments on the narcotic action no satisfactory results were obtained, the effects seen in man not being elicited from correspondingly small doses in animals. The relative efficacy of the laevo-rotatory and racemic hyoscyne was compared in man by Richards and Light (see Cushing and Peebles) without any significant difference being observed.

Professor Cushing recently asked me to compare the effects on the higher mental processes of dextro- and laevo-rotatory hyoscyne, and I have done so on two lines of investigation: first, as regards their efficacy in producing "twilight" sleep; and secondly, their effects in controlling restlessness in cases of insanity.

The twilight sleep observations were carried out at the Edinburgh Royal Maternity Hospital, on cases under Dr R W Johnstone's charge. Nearly 40 cases were recorded, but in many the drug was started late in labour, or was given irregularly. After deducting these, 27 remain in which most satisfactory conditions were observed. As far as possible the two varieties were given in alternate cases, the dosage being based on the following standard:

First hour Morphine sulphate 1/6 gr and hyoscyne hydrobromide 1/100 gr
Second hour Hyoscyne 1/200 gr
Third and subsequent hours Hyoscyne 1/450 gr

The majority of cases were primiparae. The average number of injections was twelve, a few cases received twenty or even more. For each case a special chart was kept, in which hourly progress was recorded, special attention being paid to the degree of intelligence and the state of the memory.

The dextro hyoscyne cases numbered 12. In no case was any amnesia or impairment of the intelligence observed, and in none was there any alteration in the sensation of pain. Sleep was not induced. Increase of the standard dosage caused no change in results.

The laevo hyoscyne cases numbered 15. In 10 there was complete amnesia, the patients remembering nothing after the first or second injection. They were completely oblivious to the passage of time, and although they had been a day or more in hospital many would declare that they had only just arrived. In 3 further cases amnesia was almost complete, while in 2 cases it was only produced slightly or not at all. The intelligence was markedly disordered, and often most absurd answers were given to questions. Usually after the second injection the patient lapsed into the curious dazed state of twilight sleep. These observations were made in 11 cases in labour ward, and, probably because of this, drowsiness and sleep were not always observed. Instead, the patient usually became mildly delirious, plucked at the bedclothes, and made many purposeless movements. Speech was slow and, when intelligible, showed a state of complete disorientation with rapid flow of ideas of the nature of an occupational delirium.

The question of a depressant action on the child's respiratory centre was also considered. Among the laevo-hyoscyne cases it was not unusual for several minutes to elapse before respiration was satisfactorily established. Among the dextro hyoscyne group oligopnoea was only encountered in those cases where labour had been prolonged and delivery difficult, and was therefore probably not due to the drug.

As a further experiment, 1/200 gr dextro-hyoscyne injected thirty minutes before delivery has caused no oligopnoea. An example of the failure of dextro hyoscyne may be given.

Mrs D, aged 20, of medium build. Pains began at midnight and had been constant since when she was admitted. They were coming every three minutes, the pulse was 80, the pupils half dilated, the mouth rather dry.

At 12.30 p.m. an injection of 1/6 gr morphine and 1/100 gr dextro hyo cine was given, at 1.30 another of 1/200 gr dextro-hyo cine, at 2.30 1/450 gr dextro hyoscyne, at 3.30 1/200 gr, and at 4.30 1/450 gr. The patient became drowsy at 3.30, but the intelligence and memory remained good throughout. The pulse was 72 to 80 till 2.30, 68 at 3.30 and 64 at 4.30. The foetal heart was 124 to 128 until 3.30 and 116 at 4.30. Birth occurred at 6.45 p.m. and no oligopnoea was present. The mother's pupils were normal and no amnesia was present, and but slight dryness of the mouth.

After the administration of dextro-hyoscyne a few patients became rather less restless, but it was impossible to determine whether this was due to the injection or to natural fatigue. It was therefore decided to determine the effect on cases of insanity associated with motor excitement. By permission of Dr C J Shaw, this was done at Sunnyside Asylum, Montrose, the details of the observations being kindly worked out by Dr C J Swanson.

Cases of long-standing motor restlessness were selected. Dextro-hyoscyne 1/100 gr was given to each on one occasion, and laevo hyoscyne on another. All the laevo-hyoscyne cases showed the usual sedative effects of hyoscyne, although this varied considerably in degree in different subjects. In none of the dextro hyoscyne cases was there any change observed which could be attributed to the drug, even repetition of the dose being ineffective.

Clinical Observations

Case 1—J D, female, aged 54. Toile encephale. January 6th 1925. For two days has been restless, abusive, tries to get out of bed, has had no sedatives.
11.50 a.m. Dextro hyoscyne 1/100 gr hypodermically.
12.20 p.m. Still noisy. Intelligence unchanged, pupils unchanged. This condition remained unchanged at 1.20 p.m.
January 7th. Before injection not restless, abusive.
3.25 p.m. Laevo hyoscyne 1/100 gr hypodermically.
3.55 p.m. Drowsy, but not asleep. Pupils dilated, tongue dry.
4.25 p.m. Very drowsy. Pupils dilated.
4.55 p.m. Drowsy and quiet, but not asleep. Pupils dilated, tongue dry.

Case 2—V K, aged 48.
January 6th. For months has been agitated and restless. Has been getting up open mouthed and paraldehyde given almost every night to secure sleep. Before injection was restless and getting out of bed.
5.30 p.m. Dextro hyoscyne 1/100 gr.
6.0 p.m. Unchanged.
6.30 p.m. Unchanged. Pupils unchanged.
7.0 p.m. Rather quieter.
7.30 p.m. As before.

January 9th. Before injection was restless and getting out of bed. Is attempting to compress trachea with her hands.
2.45 p.m. Laevo hyo cine 1/100 gr.
3.15 p.m. Drowsy, but not asleep. Pupils slightly dilated.
3.45 p.m. Asleep.
4.15 p.m. Awake, but quiet.
4.45 p.m. Restless once more.

Case 3—R C, aged 49. General paralysis of insane.
December 22nd 1924. Has been restless all day. Has been on chloral (30 gr.) and bromide (40 gr.) for months. Last dose at 5.30 p.m. Before injection was very restless and bumping up and down in bed.
8.22 p.m. Dextro-hyo cine 1/100 gr.
8.52 p.m. No change.
9.20 p.m. Rather less restless. No change in pupils.
9.45 p.m. Asleep.

December 24th. Last chloral and bromide at 5.30 p.m.
8.45 p.m. Laevo hyo cine 1/100 gr.
9.15 p.m. Rather quieter. Pupils dilated, tongue drier.
10.0 p.m. Asleep. Very confused on being aroused.

Case 4—A H, aged 62 years. Senile dementia. For three months has been restless and will not stay in bed. Has been getting chloral gr xx and bromide gr xliid.
December 23rd. Before injection very restless, confused and incoherent, jumping out of bed.
5.0 p.m. Dextro hyoscyne 1/100 gr.
5.30 p.m. Very restless, will not stay in bed. Pupils unchanged.
6.0 p.m. No change. Dextro hyoscyne 1/100 gr repeated.
7.0 p.m. No change.

December 24th. Last dose of chloral and bromide at 6 p.m. two days ago. Before injection very restless and jumping out of bed.
5.0 p.m. Laevo hyo cine 1/100 gr.
5.30 p.m. Still restless. Pupils dilated.
6.0 p.m. Less restless. Tongue dry.
6.30 p.m. As before.
10.0 p.m. Asleep.

From these clinical observations it would appear that only laevo hyoscyne is active in producing amnesia, in depressing the intelligence, and in controlling restlessness. The dextro-rotatory form in doses of 1/100 gr or more is apparently inert in these directions, and can only be regarded as a useless ingredient of hyoscyne when present, to be eliminated where possible.

ECTOPIC KIDNEY CONTAINING MASSIVE
CALCULI

BY

H P WINSBURY WHITE, FRCS FRC,

AS STANT SURGEON, ST PAUL'S HOSPITAL FOR SKIN AND GOUTY UREAPY
DISEASES

An interesting point in the clinical features of the following case was the fact that the pain was not located at the site of the ectopic kidney, but always in the left costo-vertebral angle. Following the nephrectomy there was again a complaint of pain in this locality for a few days.

A man aged 45 complained of constant pain in the left side of the back. It was of old standing, and on this account he had been discharged from the navy as unfit for further service nine years before. He had been in a number of hospitals during the past ten years, and although radiographic investigation had been carried out in all the cause of the pain had escaped recognition.

When I first saw the patient although he was a little thin his general condition was fairly good. The urine contained a considerable amount of pus. The radiographic examination revealed no abnormality in either renal region but in the pelvis lying mostly below the bium, occupying the hollow of the sacrum in a medial situation, was to be seen a curious irregular opacity.

On cysto copy I found the bladder to be free from stone but the seat of a chronic inflammation which was most marked about the left urteric orifice. This structure was injected swollen, and immobile. The right urteric orifice was normal in appearance and effluxes of clear urine could be seen coming from it. A ureteric catheter failed to pass up the left ureter for more than 2 cm., while 30 cm. of catheter readily passed up the right, indicating a normal length of this structure. Following the intravenous injection of 5 c.cm. of 0.4 per cent indigo carmine the dye was excreted in good concentration from the right side in three minutes whereas it had not appeared at all from the left after ten minutes had elapsed.

Microscopical examination of the urine from the right kidney failed to reveal any pus but a few Gram negative bacilli were seen. These on culture proved to be of the *B. coli* group. The urine from the bladder contained a considerable amount of pus and numerous coliform bacilli.

It was concluded from these observations that the pelvic opacities were due to a mass of calculi in the left kidney which was occupying the hollow of the sacrum, that the infection of the bladder had its origin in the left kidney, and that the right kidney was present in its normal position and functioning well. Operation was therefore undertaken with the intention of removing the ectopic organ with its stones.

Operation

With the patient in the Trendelenburg position the abdomen was opened through a left paramedian incision from umbilicus to pubes. The right kidney was felt in its normal position with no palpable evidence of disease. It was however slightly larger than normal presumably from hypertrophy. There was no kidney in the left renal region. Projecting forward from the promontory and the hollow of the sacrum was a hard somewhat irregular mass having the dimensions of a slightly enlarged kidney. The lower part of the pelvic colon and the rectum lay respectively above and to the right of the projection. On dividing the overlying peritoneum the left kidney was identified with its pelvis and hilum directed forward and somewhat to the right. It is a usual feature of a kidney in such a position for the hilum to be directed anteriorly. The whole organ was surrounded by and adherent to a considerable fibro-fatty mass and could be felt to be full of stones.

The only difficulty which I experienced with the nephrectomy arose from the fact that I was quite unable to make out where the blood vessels entered or left the kidney, on account of the extensive adhesions. This prevented several of the vessels from being identified and secured before being divided.

The accompanying figure is a drawing of the specimen after removal and from which the right side of the parenchyma and strips of the same side of the pelvis have been taken to show the full extent of the calculous formation. It is also seen that the vessels are largely aberrant, inasmuch as their connexion with the kidney is through the cortex. Two veins were the only vessels connected with the kidney by way of the hilum. It was not possible to be certain without unnecessary dissection which were the parent run's of these vessels. It is not unusual in such cases for the vessels to come from several adjacent sources such as any of the iliac vessels or the aorta.

The retroperitoneal site of the kidney was drained for forty eight hours and the patient made an uneventful recovery.

The accompanying drawing shows the extensive nature of the calculous formation, all of the dilated calyces and the pelvis were completely filled with stone. The shape of the pelvis is worthy of special attention as this structure is divided into three limbs, all lying outside the actual kidney.

From study of a radiogram it is difficult owing to the more or less medial position of the stone shadows, to decide whether the right or the left was the misplaced kidney. Such a situation of the ectopic organ is occasionally noted, but more frequently it lies over the corresponding sacro iliac synchondrosis.

In certain rare instances of pelvic kidney this is the sole renal organ. Such a contingency impresses one with the necessity of establishing the presence or absence of the other organ before the full extent of the operation is decided.

I have noted two cases from the literature in which this precaution was neglected. In one case a solitary tender left kidney lying in the left iliac fossa of a female aged 19 years was removed. The kidney was subsequently found to be perfectly healthy. The patient lived for nine days. At the autopsy the right kidney and ureter were both absent. In the other instance the only kidney, a pelvic one, was removed because it was thought to be a sarcomatous metastasis from an ectopic testis.

In considering the relative incidence of renal abnormalities, Stewart and Lodge quote the following figures from 6,500 consecutive autopsies:

Congenital absence of kidney	16 cases
Horseshoe kidney	14 "
Pelvic kidney	3 "
Unilateral fused kidney	1 case

Many post mortem examples of healthy ectopic kidneys are recorded. The majority of diseased ectopic kidneys which have been reported have been the seat of hydro-nephrosis. Calculous formation is a

far less common complication.

A SIMPLE METHOD OF DEFIBRINATED BLOOD
TRANSFUSION

BY

E F SKINNER, MA, MB, FRCP,

ASSISTANT PHYSICIAN SHEFFIELD ROYAL HOSPITAL CONSULTING
PHYSICIAN, JES OF HOSPITAL FOR WOMEN

The value of blood transfusion in certain conditions is now beyond dispute, and as a means of combating shock, either before or after operative intervention, has become almost a matter of routine.

Of all available methods, doubtless the transfusion of whole blood is physiologically the best, but the difficulties, such as to preclude its use except by a trained team, for practical purposes the transfusion of non-coagulable blood is almost universally employed.

Blood may be rendered non coagulable by the addition of some anticoagulant such as sodium citrate or by defibrination. Both methods are simple and require no very special skill, and each has its appropriate indications. I described a very simple method of transfusion of citrated blood in the BRITISH MEDICAL JOURNAL of May 5th, 1923 the blood is withdrawn from the donor's arm into a graduated bottle

of 500 ccm capacity, into which also small quantities of sodium citrate are allowed to run from time to time, according to the quantity of blood required.

I propose to describe here an equally simple method of obtaining and transfusing defibrinated blood. I assume that all the usual precautions of grouping have been previously carried out.

The apparatus consists of a wide-necked bottle, graduated in divisions of 50 ccm, with a total capacity of 500 ccm, which is a satisfactory amount of blood to give as a maximum in any one operation. The bottle is fitted with a rubber cork, through which passes a short length of glass tubing and a long stout nickel silver wire, turned into a wide flat spiral coil at its lower end. A suitable length of rubber tubing connects the glass tube with a wide-bored short-bored needle. Through the coil also passes another short glass tube connected with a Higginson's syringe, for the production, within the bottle, of a slight negative pressure. The whole of the apparatus is sterilizable, and constitutes the receiving apparatus.

The donor lies down, the flexure of the elbow is sterilized, and a tourniquet applied to the upper arm. The apparatus having been put together, with a clip on the tube carrying the needle, two or three squeezes of the Higginson's bulb will produce a little negative pressure in the bottle.

The needle is then inserted into one of the veins at the bend of the elbow, the needle being pushed in against the blood flow, so that when the clip is removed from the tube blood will flow directly along the needle into the bottle. This manoeuvre is the only difficulty, and a very little practice will render anyone quite capable of venipuncture on almost every occasion.

As soon as the bottle begins to fill, the Higginson's syringe should be gently squeezed every few seconds with the left hand, whilst with the right hand the bottle is kept constantly revolving gently, thereby swinging the blood content against the nickel spiral, which may with advantage be slightly roughened by filing. As soon as sufficient blood is obtained the needle is withdrawn, the Higginson's syringe detached, and the bottle continuously rotated for about six minutes, at the end of which time the cork is removed, a large single clot of fibrin will be found adhering to the spiral.

The rest of the blood should be, and generally is, absolutely free from any fibrin, but to make it quite safe it must be filtered. This has proved one of the difficulties of the method, but I have recently used a special fritted glass filter instead of glass wool or silver gauze, this solves the problem of filtration. This filter is made by Schott and

Gen, Jenr, and is numbered 11aG3/2-3, it has a mesh of 100 to 110 microns, and allows the passage of blood quite easily, it can be washed free from fibrin afterwards, and can be sterilized without fear of damage.

A convenient receptacle for the filtered blood is a mercury container, to the end of which is attached a rubber tube provided with a clamp and needle attachment. The filter is inserted into the open end of the mercury container and the defibrinated blood poured through the filter. It is now ready for administration.

It is not always easy, in a collapsed patient, to bring the needle on the end of the tube has entered the vein comfortably, and I now invariably employ a 10 ccm Record syringe fitted with a small Harrison's tip, which also fits the ordinary Wassermann needle.

With the tap open and the syringe piston well down the needle is pushed directly into the recipient's vein (in the opposite direction to that when taking blood from a donor), and if the needle is comfortably in the vein a slight withdrawal of the piston will give proof. The tap is now turned, the syringe detached therefrom, and the tube from the receiver, with a suitable metal adapter, is pushed into the tap, which is again turned, and blood will begin to flow into the vein.

The recipient's vein is made prominent by the application of a tourniquet, as in the case of the donor, and this, of course, must be removed as soon as it is certain that the needle is in the vein.

PERIODIC SWELLING OF THE SALIVARY GLANDS

UNDER this heading a condition is described in Osler and McCrae's *System of Medicine*. The following brief notes of a case will be of interest because of the rarity of the disease and because a certain line of treatment was followed with apparent success.

A retired schoolmaster aged 62 was seen by me with Mr. H. G. B. Blackman. He gave a very intelligent account of his attacks. The first was in 1916 and since then there have been two or three recurrences each year and at any season. Without assignable cause and while feeling perfectly well the attacks commence with aching and stiffness at the angle of the jaw on both sides. This is followed within a few minutes by dryness of the mouth and by sneezing. Then the two parotid glands begin to swell simultaneously and symmetrically. They are tender and there is considerable disfigurement. After a few hours the mouth regains its moisture, the sneezing ceases and the parotid swellings begin to subside but their reduction is not complete until the third day.

This recurrent malady has been ascribed to plugging of Steno's duct by calculus or by inspissated mucus. But in my patient the simultaneous affection of both parotid glands excludes such an accidental cause. The same argument would apply to an infection of the ducts or of the glands. Sir H. D. Rolleston, writing to me on the subject, suggested "asthma of Steno's duct," and the constant association of sneezing in my patient's attacks seemed to support the idea. At the commencement of his last attack he was given hypodermically 3 minims of adrenalin solution. The whole attack was at once brought to an end and within an hour the swelling of the parotids had gone. This has not happened in any previous attack.

CALCULUS IN THE TESTES

A man, aged about 30, consulted me in the Bhuj Civil Hospital for a chronic sinus in the right side of the scrotum, which had existed for more than eighteen months. There was some pus coming out of the sinus, it was hard, and I suspected a haematoma or a malignant tumour or tubercle in connexion with the testes. There was a history of tapping, by which I thought a haematoma might have been caused. The patient had some rise of temperature regularly in the evening. He was admitted to the hospital, and under chloroform an incision was made about 3 inches

long parallel to the sinus. On sitting open the sinus I found a calculus about the size of a hen's egg without its shell. As the long duration and septic condition had done much damage to the testis I removed it, excised the whole of the sinus tract, and closed the wound. It healed by first intention, and the patient was discharged in about ten days. The specimen has been preserved with a view to presenting it to the Robertson Medical School at Nagpur.

I do not find any mention of the formation of a calculus in the body of the testes in any of the books on surgery or urinary diseases that I know. In my practice of over twenty-five years in charge of large hospitals I have never come across a similar case.

REMOVAL OF PAROTID TUMOUR WITHOUT APPLICATION OF ANY LIGATURE

A woman, aged 68, was admitted to the County Mental Hospital, Lancaster, with the parotid tumour shown in Fig 1. At about 40 years of age she was operated upon for tumour of the breast, which a daughter states was cancerous; she had also had operations for appendicitis and gall stones. After the withdrawal of some teeth eight years ago a small pea-shaped body appeared which gradually increased in size. The tumour was found to be fairly hard, deep seated, and attached at the lower pole; the skin was stretched and glossy over the most prominent part.

On February 11th, 1925, I removed it, and although

FIG 1.

FIG 2.

bound to the deep tissue by dense fibrous bands it came away intact, it was slightly larger than a hen's egg; no ligatures were employed except for approximating the skin surfaces. Then pressure was applied by a pad of wool, and healing by first intention took place. The patient was up in a week, and her appearance in three weeks is shown in Fig 2. A section made and stained by Dr S. R. Tittersall showed that the tumour was chiefly of a myxomatous character, with a small cystic portion at the upper pole; there were numerous fibroblasts posteriorly, due probably to the chronicity, but there was no sign of malignancy, which, I believe, is very frequent in a tumour of this type and patient of this age.

RECTAL ETHERIZATION IN SUITABLE CASES

Rectal etherization has not gained much popularity in this country. As a routine method of inducing anaesthesia it is unsuitable in a busy general hospital, but in certain cases, when the more orthodox methods are strongly contraindicated, it is of undoubted value.

A man, aged 46, was admitted to the hospital suffering from acute cholecystitis. His general condition was bad as he was suffering from marked emphysema and aortic incompetence. On two previous occasions he had been operated on for gall stones and on both occasions he

As open ether was used as local anaesthesia resulting from the two chest conditions, as owing to the

heart conditions we considered spinal anaesthesia too dangerous, we decided to employ rectal etherization.

About four hours before operation the lower bowel was washed out by enema, and three hours later 1/4 grain morphine and 1/100 grain atropine were administered hypodermically. A warm mixture containing 6 oz. ether and 2 oz. olive oil was slowly run into the rectum (1 oz. in 5 minutes) by means of a funnel, rubber, and catheter. During the introduction of the oil and ether mixture the patient micturated and had an intense desire to defecate but on clamping the catheter this desire passed off.

About ten minutes later he had to use his own 'store' pins and needles in his legs, and twenty minutes later he showed all the signs and symptoms seen in the excitement stage of ether anaesthesia. He was then taken into the operating theatre and to complete the induction about 1 oz. of ether was administered by the open method. With this additional ether he remained in a state of surgical anaesthesia for one hour. The gall bladder was exposed in the usual manner and drained. During the operation there was complete muscular relaxation, the respirations were quiet and easy, and at no time did the patient present any untoward symptoms.

On his return to the ward the lower bowel was thoroughly washed out by soap and water enema and saline. There was no post-anaesthetic vomiting and the patient slept for about ten hours after the operation.

A CASE OF ECTOPIC GESTATION

In the case of ectopic gestation here reported an ovarian gestation about twenty-six weeks old was found on the right side, and a tubal gestation about eight weeks old on the left. According to Dr Lee only seventy-two cases of ovarian pregnancy had been recorded down to 1921. Bilateral cases of the tubal type have been reported from time to time, but double cases of such a mixed type as in the present case must certainly be extremely rare. Ectopic gestations of the ordinary type are fairly frequent in Central America. Dr V. C. Reynolds, senior surgeon of the Vicente d'Antoni Memorial Hospital, to whom I was indebted for permission to publish this note, states that he has operated on about ninety such cases in fifteen years of practice.

A woman, aged 30, married for fourteen years, nulliparous and of spare build, was admitted to hospital, complaining of a tumour abdominal discomfort, loss of weight, occasional pyrexial chill, constipation and amenorrhoea for eleven months. Two months earlier she had had a bloody discharge from the vagina accompanied by much pain on the left side of the abdomen. She believed this to be a return of menstruation, but she had no period in the following month. She had noticed the tumour some six months previously. The swelling had progressively increased in size from that time but had ceased growing latterly. She was never inconvenienced in any way apart from the natural sensation of weight caused by the tumour itself.

In the abdomen a prominent swelling about the size of a six months gravid uterus was obliquely inclined towards the right side. It was elastic, tense and fluctuating. On the left side there was another tumour of smaller size, closely related to that on the right. No tenderness was present and on auscultation nothing could be heard. The cervix appeared to be slightly softened and tilted back. The wide and shallow anterior fornix was occupied by a firm mass, while the posterior was deep and narrow. The position of the uterus was not definitely ascertained; it seemed to be retroposed, as suggested by the angular position of the cervix, due undoubtedly to the large tumour in front. The cervix moved with the tumours above it; this sign suggested a uterine tumour but could be otherwise explained. From these clinical findings we made a diagnosis of cystic ovaries.

A median laparotomy was performed five days later, and on laying open the peritoneal cavity the tumour presented a looking very much like an ovarian cyst. Posterior adhesions to the omentum and abdominal wall were broken down; the tumour was displaced from its bed and clearly defined. The uterus was found to be slightly enlarged and the Fallopian tube on that side was stretched over the posterior inferior aspect of the cystic swelling with apparently normal ostium and fimbriae. The right ovary could not be found; it seemed that the tumour had replaced it. Foetal parts were felt in the swelling and the nature of the case became evident. Exploration on the left side of the pelvis established the presence of two swellings close to each other: (a) a blood cyst of the ovary, and (b) an elastic enlargement of the left Fallopian tube. The tumour on the right was next incised and a papaceous mass foetus about six months old was delivered. It appeared to be well developed, was fourteen inches long, and had a fair amount of hair on its head. On the left side a partial oophorectomy and a salpingectomy were performed and the abdomen was subsequently closed. The left tube was found to be dilated into a sac with a foetus about eight weeks old inside its amniotic membrane. The patient made an uninterrupted recovery.

The tumour on the right side was unquestionably an ovarian pregnancy, which had grown between the two layers

of the broad ligament. The relation of the tube to the sac wall seemed to prove this, besides the total absence of ovarian tissue on that side. The interesting points in the case are the long duration of the gestation, the lack of distinctive symptoms, and the impregnation of the opposite tube, which caused the patient to seek medical advice.

ACUTE THYROIDISM FOLLOWING LIGATION

Acute thyroidism following ligation of the superior thyroid artery must be very rare. The following case affords an interesting example. My thanks are due to Dr R. A. Young for allowing me to publish it.

C. J., aged 23, was admitted to hospital with a large vascular goitre and extreme exophthalmos. The symptoms from which she had been suffering for six months were distressing. The temperature was normal, pulse 104 and regular, pulse pressure high. Flushings of the face and neck, tremor and general excitability were very marked. The superior thyroid arteries were enlarged and tortuous, a thrill being present on both sides. Small adenomata were present in both lobes of the enlarged gland. The patient was kept at complete rest and given a course of bromides for three weeks. It was then decided to ligature the superior thyroid arteries with a view to partial thyroidectomy at a later date.

Operations

A small injection of morphine and scopolamine was given and the right artery ligatured under local anaesthesia (novocain 1 per cent). The patient's condition was splendid after the operation and distinct improvement followed. After a week the nervousness and excitability had abated in rather a dramatic manner. Pulse 100.

A fortnight later the left artery was ligatured. A small injection of morphine and hyoscine was given and the operation performed under local anaesthesia. After the operation the patient appeared

was drowsy and very drowsy. The breathing became stertorous and coma set in. Three hours later the temperature rose to 103° F, pulse 150 and acute oedema of the lungs supervened. Oxygen by the nose, atropine and strychnine were given and the colour improved slightly. After a short lapse the temperature rose to 105° and the pulse became uncountable. Tepid sponging brought the temperature down to 104° and further injections of atropine were given. The condition of the patient improved and she became restless. Eight hours after the operation she regained consciousness.

Day by day slight improvement was noticed but she still suffered from mental confusion and extreme drowsiness. The temperature reached normal after five days, and remained steady for five days the pulse was 120.

Acute stomatitis and parotitis now retarded the progress and nourishment was taken with great difficulty. Rectal and intravenous salines were given. The patient went rapidly downhill and pulmonary oedema again set in. A rigor, an uncountable pulse and a final rise of temperature to 108° F were the main features before death.

A case of exophthalmic goitre which ended fatally from acute thyroidism was published in the records of the Middlesex Hospital of 1899.

A woman aged 32 was admitted with a vascular goitre marked exophthalmos and a regular pulse of 102. Three weeks later she became very dull and drowsy and at times restless. The temperature rose suddenly to 103° F and the pulse increased to 160. Stomatitis complicated the attack. Later the pulse became uncountable and death followed.

These two cases show a marked similarity in their symptoms, and are interesting as they demonstrate acute thyroidism (1) following ligation and (2) occurring without surgical intervention.

House-Physician Middlesex Hospital

Reviews.

A FRENCH VIEW OF FREUDISM

Any novel doctrine is faced with two dangers—the enthusiasm of over-zealous proselytes and the opposition of over-doubting sceptics. The proselyte may damage the doctrine by hasty application to unsuitable conditions, the sceptic may hinder progress by hasty condemnation on based on insufficient examination. In the *BRITISH MEDICAL JOURNAL* of December 6th, 1924, an account was given of Professor Paul Sollier's summary of the proceedings at six conferences on psychology held in the Institut des Hautes Etudes de Belgique, at which an attack was made on the doctrine of Freud. Sollier said that some of Freud's enthusiastic disciples declared that henceforth psychology would be divisible into two periods—namely, before and after Freud, while some opponents described the teaching as the scholasticism of pinnographic metaphysics. The views of Dr J. LAUMONIER, professor at the Ecole de Psychologie de Paris, are perhaps similar to, but milder than, those of Professor Sollier. His book, *Le Freudisme Exposé et Critiqué*, is readable and well arranged.

The first three chapters contain a statement of the doctrine of Freud, a description of psycho-analysis and its methods, and an account of the application of psycho-analysis to normal life, individual and collective. Dr Laumonier's criticisms are reserved for the fourth and last chapter. In this he begins by classing the doctrine of Freud with the conceptions of Rousseau and the theories of Marx, as a mystical form of religion which attracts fervent adepts who are captivated by the apparent logic of the system. The Freudians, without inquiring into details, accept the truth readily because it attempts to render comprehensible a multitude of facts which have been much neglected—for example, dreams, forgetfulness, and lapses in speech. Dr Laumonier thinks that in some cases a welcome is extended to the doctrine because it legitimizes, or at least excuses, tendencies to which many people are ready to yield. It makes a retrogression in that it reinstates the disorganizing power of sexual impulses which education had succeeded in moderating. He dwells on the difficulty of meeting the arguments of the Freudians, in that for their refusal to accept their dogmas only prove that the sceptic is a prey to the resistance of his repressed complexes, in fact, the critic either lacks sincerity or clarity of vision. It is contended that those who have not practised the rites cannot judge of their merits.

According to Dr Laumonier the fundamental error of Freud was his belief in a normal infantile sexualism. This *a priori* conception vitiated in advance Freud's direct observations of children, he used the eyes of adults initiated into sexuality when observing the actions of children, and attributed to them the idea of perversion because analogous actions are seen in adult perversities. If a little boy and girl play at being husband and wife, what reason have we for supposing asks Dr Laumonier, that their gestures correspond with the emotions felt by their father and mother in the same circumstances? In most cases, even where children have undergone visual or auditory initiation into sexual matters, there has been no observable trace left of emotional disturbance, simply because the child knew nothing of the significance of the action. The interest was no greater than that aroused by listening to the "tick, tick" of a watch. Experimental evidence has shown that sexuality is bound up with the maturation of the genital organs, and the pouring of their secretions into the general circulation. Normally the infant affords no evidence, histological or physiological, of internal genital secretions. Except in cases of exceptionally early development infantile sexualism in the proper sense of the word does not exist. Freud's belief in this sexualism came, says Dr Laumonier, mainly from his analysis of dreams and of neurotic symptoms, an analysis which led him to imagine in the adult unconscious erotic tendencies derived from the tenderest age. Notwithstanding the prodigious activity attributed to the infantile libido, the recollections of his

Le Freudisme Exposé et Critiqué. Par le Dr J. Laumonier. Paris. Felix Alcan. 1925. (Cr. 8vo pp. 172. Fr. 9.)

in infancy refer generally to events of small importance, never or hardly ever to sexual happenings. To explain this singular elective amnesia Freud imagined a mechanism of repression or resistance.

At this point in his criticism Professor Laumonnier complains that Freud has not defined his terms properly. The word "unconscious" should be limited to impressions which have never reached perception, such as the action of the sympathetic or the vagus, to impressions which have been perceived but have been forgotten the word "subconscious" may be applied. To these terms Freud, in his anthropomorphic description of the human mind, adds a third, the "preconscious," which he applies to tendencies (or sums of impressions) which his repressive guardian permits to cross the threshold of consciousness, though they do not even then become conscious unless they succeed in attracting the attention of consciousness. By confusing the terms "unconscious" and "subconscious" Freud has been able, according to the needs of his argument, to attribute to actual tendencies the quality of reminiscences of past tendencies. This explains why Freud so often takes the present aspirations of his patients for old aspirations forgotten or repressed, which originated in infancy. By confounding actual perceptions with reminiscences of the past Freud came to regard the unconscious as the real psyche, and his teleological organization of censors and resistances, his struggle between the *libido* and the *ego*, between pleasure and reality, between life and death, are simply a reproduction of the mystical idea of opposing principles, which is common to all religions.

The introduction of so many confusions and finalistic hypotheses into a doctrine intended to be scientific is explained, according to Dr Laumonnier, by the errors of Freud's methods, of which the principal were the interpretation of symbols and the analysis of the association of ideas. Freudian symbolism is not always in accord with popular symbolism. Why prefer the Freudian symbolism, asks Dr Laumonnier, when, on the one hand it justifies psycho-analytic interpretation by the traditional symbolism, and, on the other, applies psycho-analytic symbolism to the interpretation of historical and legendary symbols? If a drunkard dreams of bottles is it necessary to assume that he is the victim of an erotic complex which is seeking to reach the light of day? The psycho-analyst replies that if we explore the association of ideas we arrive invariably at an unconscious sexual tendency which is expressed by the symbol of a bottle. To this Dr Laumonnier retorts that there is no proof that symbols have always the same significance, or that they do not change with the epoch, the race, or the environment, and that while it is certain that dreams follow rules that we do not know as yet, there is nothing to show that they are compelled to follow the rules imposed by Freudism. To the method adopted in the exploration of the association of ideas, Dr Laumonnier objects that the associations are not entirely free or spontaneous, but that they are directed or provoked by the psycho-analyst. Almost always at the second or third sitting, the doctor makes an allusion which orientates the patient's ideas in a certain direction. In this way different doctors may arrive at different results in the same patient. Dr Laumonnier notes also that a patient only says what he has already felt or learnt, and that it is impossible to make him talk of matters, such as some of the rarer perversions, of which he has no notion.

The vicious circle of Freudism is, the author says, that it has first to admit an infantile sexualism so extraordinary that a censor, repression, and resistance must be invented to explain why the adult has no recollection in the matter, and, secondly, it has to admit the part played by this sexualism in the causation of neurosis, because it is in analysing symptoms that psycho-analysis discovers the *libido* of the infant and its conflict with the *ego*. Freud committed an initial error in method by attributing to the fundamental mentality of the subject ideas which he himself has artificially introduced. Psychoanalysts who have the faith always find a pathogenic sex complex, while psychiatrists, holding no preconceived ideas, more often find totally different motives—family differences, illnesses, fire, shipwreck, ruin or mourning.

Dr Laumonnier then discusses the cures attributed to psycho-analysis. Cases suitable to the treatment are limited to those of neurosis of transfer, and proof that the treatment is finished rests on the intuition that the important complex has been found and laid bare. As the patient nearly always protests energetically against the existence of the tendencies or desires, it is necessary to insist strongly for a long time, until he finishes by admitting their existence. But whether he does so because the tendency is a fact, or because he wishes to get rid of the importunities of the doctor, no man can tell. According to Dr Laumonnier many patients treated by psychoanalysts drift into other hands and are ultimately cured without the introduction of sex complexes. Others develop some other form of neurosis, sometimes of a sexual character, which may have taken its origin in the psychoanalytic treatment. In many cases the cure is not due to the exposure of a sex complex but to the confidence placed in the doctor, or to the fact that the kind of neurosis most suitable for the treatment has a tendency to disappear spontaneously.

At the end of his book Dr Laumonnier adds a conclusion. He does not accept the statement of M. A. Delmas that "in the Freudian psychology there is both good and new, but that which is new is not good, and that which is good is not new." Dr Laumonnier, while finding that neither the doctrine nor the method of Freud can be taken seriously from the scientific point of view, thinks that there are certain materials in Freud's artificial construction which can be used for building a more solid edifice. Freud exaggerates the influence of sexuality, but we may do well to recognize it more frequently in many phenomena such as in dreams in plays on words and in artistic manifestations. Sexuality is not alone responsible for the formation of character but it indicates some of the motives of fundamental perversity. Freud's ideas on the origin of societies and religions and on the extraordinary importance of the Oedipus complex, throw light in some cases on myths and legends and render them comprehensible. He has done an enormous amount of work but being a mystic he has given to phantoms the appearance of realities. His doctrine has spread throughout the world like a religion, and many have accepted the faith because it professes to explain everything under cover of a new science. The danger feared by Dr Laumonnier is that it may excite a perverse curiosity in the public owing to its pretension to establish psychology, morals, and the history of civilization on a new basis.

The conclusion to be drawn from the views of Dr Laumonnier would seem to be that while the doctrine of Freud is worthy of further, and really scientific investigation, it is unjustifiable, in the present state of knowledge, to apply it indiscriminately as a method of treatment. It is perhaps unfortunate that, as in the case of mesmerism and hypnotism, the only material for investigation is the human being. In the process of investigation much harm may accrue to individuals.

THE "EXTRA PHARMACOPOEIA"

THE *Extra Pharmacopoeia* of MARTINDALE and WESTCOTT is a very old friend to the medical profession, and we note with regret the death of Dr Martindale's collaborator, Dr Wynn Westcott, which occurred while the volume under review the second volume of the eighteenth edition, was in the printer's hands.

Most of our readers will be aware that the *Extra Pharmacopoeia* is divided into two volumes the first deals with matters relating to treatment while the second is devoted to analysis, experiments, and research. The field covered by the second volume is a very wide one, and the authors mention in their introductory leaflet that the labour involved in its preparation is enormous. This we can well believe, for a large proportion of its contents is derived directly from original papers or from actual experimental work. Anyone who has had occasion to collect the

The *Extra Pharmacopoeia*. Dr W. H. Martindale, Ed. D. and W. Wynn Westcott, M.B. Eighteenth edition, vol. II, London, H. K. Lewis and Co. 1925. (Keap 8vo pp. xlii + 728 20s net.)

original information upon a single one of the hundreds of subjects dealt with in this volume will be able to form an estimate of the labour involved in its preparation. The book contains over 700 pages of small print, covering, as we have remarked, a very wide range of subjects, and it is, of course, impossible to deal adequately in a short review with a reference book of this size and scope. Fortunately the *Extra Pharmacopoeia* is so well known that it is unnecessary to do more than mention a few of the most striking new features.

The organic arsenical preparations are dealt with at length, and a description is given of the methods of biological standardization evolved in the laboratories of the Medical Research Council. An account also is given of the methods of biological standardization used to determine the potency of extracts of endocrine organs. The chapter on foodstuffs is of particular interest. Here will be found a short account of the properties and distribution of vitamins. An exhaustive account is given of the various processes employed in the preparation of flour. Details are given of the bleaching of flour, of the chemistry of baking powders and of flour improvers, and the distinction between the various types of flour is explained shortly. In a later chapter in the book information is given on the subject of food preservatives. No fewer than 60 pages are devoted to radiology and radium. Useful tables showing the physical properties of the radio-active elements are provided, and full details are given of the technique and results of treatment with x rays and radium.

The volume contains a host of facts concerning the physiological and chemical properties of drugs, extensive tables for organic analysis, and a comprehensive account of the properties of the known pathogenic bacteria. The effort that has been made to keep the work absolutely up to date is indicated by the fact that a reference is given to the papers of Gye and Barnard on the filterable cancer virus. It is five years since the last edition of this volume appeared, and the present volume contains a remarkably large amount of new information. Medical science is advancing and expanding at an ever-increasing rate, and the authors of the *Extra Pharmacopoeia* have been extraordinarily successful in keeping abreast with this advance in knowledge.

INTERSTITIAL KERATITIS

WIDELY different views are held on the most satisfactory method of treating interstitial keratitis, and of the value of arsenical medication in this disease, on this subject even the standard ophthalmological textbooks are far from being unanimous. Mr LINDSAY REA has of late devoted much attention to the matter, and some months ago communicated his impressions to the Ophthalmological Section of the Royal Society of Medicine, lately, at the British Medical Association Meeting at Bath, in a paper published in this issue (p 509), he further elaborated his general thesis. The first of these is now published in a small volume entitled *A Preliminary Report on the Treatment of Interstitial Keratitis*.¹

Despite the title, three quarters of the essay is concerned with the etiology and clinical manifestations of the disease. As regards the former, he entertains no doubt whatever 100 per cent of his cases are syphilitic. Even when the Wassermann test is negative, more delicate tests, such as Lunge's colloidal gold reaction, invariably show a luetic type. He can find no suggestion that tubercle is a causal factor, and considers trauma of small importance in the etiology.

For comparison in treatment the cases are divided into three categories: untreated cases which had never had antisyphilitic treatment, cases which had not received treatment until some months after the onset of the disease, and cases treated promptly and intensively. The standard of results is taken to be, not the amount of evident pathological residua, but the degree of visual acuity finally obtained—a very common sense basis of judgement, inasmuch as the eye is an optical organ whose primary function is that of vision. Judged by this test—the end-results of

vision finally obtained—the author finds that the results in the first two series were practically alike: invariably greatly lowered vision, sometimes blindness, many patients had choroiditis or strabismus, and the majority showed deafness in more or less degree. In the third series, on the other hand, wherein treatment consisted of the local administration of atropine, with prompt, long-continued, and intensive constitutional treatment with organic arsenical preparations combined with iodides, not one result was comparable with the former. Although, however, undoubtedly beneficial, the effect of this thorough regime is by no means dramatic, the average time for cure in his cases is eight months, patience is necessary, and relapses are not unknown.

The impression conveyed by this record of ninety-one cases, carefully studied clinically and carefully followed up, seems to bear out fully Mr Rea's later conclusion expressed at Bath: "If the majority of cases of ocular syphilis are treated vigorously with such preparations as novarsenobillon the results, although not dramatic in suddenness, are consistently good", a conclusion interesting to compare with that expressed by Jonathan Hutchinson, who, while satisfied with the superior efficacy of antisyphilitic treatment (in his case mercury and iodides), wrote originally, in 1858 "I would carefully guard my readers against expecting too much from them."

D L

HAEMOGLOBINURIA DUE TO COLD

Dr SALÉN's book on haemoglobinuria due to chill,² a less comprehensive term than the name "paroxysmal haemoglobinuria," contains a full and prolix account of his observations and researches into the pathogenesis of that comparatively rare disease. The author distinguishes it from the forms of haemoglobinuria due to physical exercise, whether mild or violent, termed "marching haemoglobinuria" from their occurrence among soldiers. About the end of last century there were, he says, three chief theories as to its causation. The first supposed that exposure to cold brought about a local haemolysis in the chilled blood vessels, leading to a general haemoglobinaemia which produced the other symptoms. The second theory attributed the disease to an anomalous constitution of the red blood cells, mechanical injury, an increased CO₂ content, a primary vasomotor upset, and the production of haemoglobinaemia by a general peripheral haemolysis. The third theory supposed the haemolysis to be extravascular and intrarenal, and attributed it to an abnormal physico-chemical constitution of the blood. All these views were naturally much modified by the work of Bordet and of Ehrlich and Morgenroth on the haemolysis of blood serum, and in 1904 Donath and Landsteiner concluded that the blood of haemoglobinuric patients, examined *in vitro*, contained an amoceptor which became activated by exposure to lowered temperature and sensitized the red cells for the action of the complement in the serum. Dr Salén endeavours to submit this explanation to a more complete analysis, for it has been uncertain how far the processes *in vitro* are identical with those *in vivo*, and exactly how they proceed *in vivo*.

Some six hundred pages of his book are occupied with details of his own serological and clinical observations and their discussion in the light of the literature of the subject, but the whole is summarized in the last sixty pages. He finds that haemoglobinuria from cold exists in two forms—the latent and the manifest, both usually occur in patients with tertiary syphilitic or metasphylic lesions. Both classes, manifest and latent, are found to have the cold-haemolysin or cold amoceptor in their blood. Patients showing this abnormality in the blood may react in four different ways on exposure to cold, as follows (p 623):

(1) Haemoclastic crisis and clinical shock with sensitization of the red cells, haemoglobinaemia and haemoglobinuria, diminution in the number of the red cells, and increased excretion of urobilin substances in the urine. (2) Haemoclastic crisis and clinical shock, with sensitization and diminution of the red cells, haemoglobinaemia and haemoglobinuria not recognizable, transient albuminuria and increase of urinary urobilin, possibly a slight intravascular dissolution of the blood. (3) Haemoclastic crisis and clinical shock with sensitization and diminution of the red cells.

¹ A Preliminary Report on the Treatment of Interstitial Keratitis. By R. Lindsay Rea, M.D., F.R.C.S., London: H. K. Lewis and Co., Ltd., 1925. (Demy. 8vo. pp. 32. 4 plates. 2s. 6d. net.)

² Studien über die Kältehaemoglobinurie. Von Ern. B. Salén. Acta Medica Scandinavica Supplementum VI. Stockholm: Isaac Marcus, 1925. (Med. 8vo. pp. viii + 70. 7 figures.)

No haemoglobinemia haemoglobinuria, or albuminuria, but a transient increase in the urinary urobilin. (4) No haemolysis crisis, shock or sign of dissolution of the red cells. The effect of the cooling is shown only by a diminution in the number of the red cells and a transient increase in the urinary urobilin.

Patients with manifest haemoglobinuria fall into the first two classes, the latent into the last two. Salen quotes the case of a man who suffered from the manifest form of the disease for forty years, and then passed into the latent class, in which he has remained for the last four years. This improvement is set down to a thorough course of antisyphilitic treatment, and the use of a series of cold foot-baths to burden the patient by destroying (haemolysing) his older red cells. Salen argues that it is the older red cells that are first destroyed in an attack of haemoglobinuria from cold, the destruction must be extravascular in the latent cases, intravascular in the manifest. In all cases the blood serum when cooled and examined by the ultra-microscope shows a change in the physical condition of the dispersed colloids, presumably globulins, which are precipitated in relatively large particles, and in extreme cases may present a macroscopic agglutination similar to that seen in a positive Sachs-Georgi reaction. Salen assumes that this physical change on cooling sensitizes the red cells and has them open to the attack of the haemolysin that may or may not be present in the circulating blood. The proteins thus altered by cold may be supposed to act as heterogeneous colloids in the organism and to produce the signs of shock in cases of the first three classes of haemoglobinuria set down above.

There is a certain ambiguity in Salen's classification of haemoglobinuric patients, as on page 657 he gives a classification that is not the same as that on page 623. The connection between syphilis and haemoglobinuria he leaves uncertain, though he believes it to be close, remarking that further investigations are required before the question can be settled. He holds the name "haemoglobinuria due to cold" to be misleading, as haemoglobinuria is often absent in cases naturally belonging to the class, and he suggests "urobilinuria due to cold or chill" instead. His last word on the pathogenesis of the disease is that it may fairly be regarded as an impairment of the normal metabolism of the blood and the mechanism that normally brings about the disappearance of the red cells, due to a syphilitic infection. The normal mechanism for their elimination must be supposed either to fail or to act in an abnormal manner.

"PYE'S SURGICAL HANDICRAFT"

THE appearance of the ninth edition of *Pye's Surgical Handicraft* is welcome, for it is an old favourite among students. The new edition has been edited and largely rewritten by Mr. CLAYTON GREENE. This book is especially designed to help house surgeons and dressers. It presents to them surgery in the etymological sense of the word—a fine art demanding much manipulative skill—and impresses on them that their time in the wards is really a practical apprenticeship to their handicraft. The book contains a detailed account of all the minor work which is in most cases left for them to deal with, gives hints in diagnosis and treatment, sounds useful notes of warning, and tells them when to consult their chief. There are eleven sections. The first deals with the arrest of haemorrhage, and contains a useful account of blood transfusion. The second discusses bandaging, trusses, and splints. The third treats of dislocations, and sprains, and the fourth treats of wounds, ulcers, and burns. The next gives a general account of the venereal diseases. Cases requiring prolonged mechanical treatment, such as tuberculous disease of the hip and spine are grouped together in Section VI. The next section deals with a variety of subjects, such as the excision of joints and serious cystitis and the use of catheters and other instruments in the bladder, the manner of employing the stomach pump and of giving hypodermic injections, the use of bougies, the administration of enemata, the treatment of haemorrhoids, and the

performance of various minor operations. The eighth section is devoted to the special departments—eye, ear, nose and throat, and the teeth, and the ninth discusses certain emergencies, both surgical and general, such as poisoning, drowning and suffocation. The tenth section deals with anaesthesia, and the eleventh with miscellaneous subjects, such as the preparation of patients for operation and their after-treatment, urine testing, and the uses of x-rays in diagnosis and treatment.

The text is supplemented by some 344 illustrations and 14 plates. We can strongly recommend this book, not only to those to whom it is especially addressed, but also to general practitioners and those working in clinics.

NOTES ON BOOKS

THE Anatomical Society of Great Britain and Ireland, besides publishing a *Journal*, was formerly in the habit of issuing, three or four times a year, records of its proceedings as separate publications. In these were given the titles, and occasionally abstracts, of the papers read before the society. Later it became the custom to discontinue the *Proceedings* as separate publications, but to issue them as part and parcel of the *Journal*. Yet another practice is now initiated in the publication, in one separate volume, of the *Proceedings* for the four years 1921-25, a further change being that in addition to the notices of the papers read a record is included of the subsequent discussions. The volume is published under the auspices of the society, which has had for the purpose the advantages of Dr R. J. Gladstone's services as recorder and those of Professor J. Barclay Smith as editor. The publication reflects the greatest credit on all concerned, and we are confident that it will be found to meet a real want on the part of those members of the profession who, while not primarily anatomists, are still anxious to obtain a succinct account of the advances that are being made or have recently been made in anatomical science.

DR C. C. MILLER of Chicago, in his book on *Cosmetic Surgery*, gives to the profession the author's ripe experience on a subject which has been the happy hunting ground of the numerous quacks and the so-called beauty specialists. That there should be any great demand for this particular type of operation must be construed as evidence of a tendency to retrogression in those who demand it. One would imagine that its field of usefulness would be strictly limited, but the author says "With the tremendous change in the character of the people and the developing of a pleasure-loving race in place of the more serious types of the past, there has come more or less of a demand for cosmetic operations." In contrast to this we may recall the words of a great man at a sitting given to an artist: "Paint me as I am, for if you leave out one furrow or wrinkle not a halfpenny will you get for your trouble." The book is full of effective and painstaking advice to the surgeon willing to embark on such operations, and it is liberally illustrated. The author performs his operations under local anaesthesia, he deals mainly with the following subjects: folds, bags and wrinkles about the eyes, face lifting operations, operations for double chin, subcutaneous sectioning of face and neck structures for the eradication of lines and wrinkles, formation of dimples, various plastic devices for deformities of the nose, ear, and mouth. The greatest degree of success, the author says, demands an artistic eye, and study of the features by means of photography, combined with a knowledge of how to cut and how to sew. For the latter he uses interrupted sutures of fine silk on cambric needles.

In the little book, entitled *Chemistry to the Time of Dalton*, which forms the third volume of the Oxford Chapters in the History of Science, edited by Dr. Charles Singer, Mr. E. J. HOLMYARD has given an excellent sketch of the history of chemistry from the earliest times to the establishment of the atomic theory by John Dalton at the end of the eighteenth century. The book contains eight chapters devoted respectively to chemistry in Greece, Egypt, and Islam, chemistry in Europe until the fifteenth century, the progress of chemistry from Norton to Glanville, the phlogiston theory, Boyle and his contemporaries, Black, Cavendish, Scheele, and Priestley, Lavoisier, and Dalton. The text is accompanied by numerous well-chosen illustrations.

* *Pye's Surgical Handicraft*. Edited and largely rewritten by W. H. Clayton Greene. CBE. B.A. M.D. B.C. Camb. F.R.C.S. Eng. Ninth edition fully revised. Bristol: J. Wright and Sons Ltd. London: Simpkin, Marshall, Hamilton, Kent and Co. Ltd. Toronto: The Macmillan Co. of Canada Ltd. 1924. (Demy. 8vo pp. xvi + 619. 344 figures. 14 plates. 21s. net.)

The commonest ailment in these temperate zones is the common cold. It would appear to be so also in the United States according to the statement of Dr. RUSSELL L. CECIL of Cornell University who has written an illuminating little book on the predisposing and exciting causes of these ailments. The book is intended for the layman. It is written in simple and pleasant language. At the same time it is strictly scientific—that is to say it gives an account that any professional man will recognize as true according to the known facts. It begins with an account of the anatomy of the respiratory passages, deals with varieties of colds and gives attention to hay fever and asthma, tonsillitis and influenza. Then there is a few some chapter on the complications of colds which is calculated to send every sufferer post haste to his physician. Yet the picture is not overdrawn. Finally, the author deals broadly with the questions of treatment and prevention, and discusses freely the use of vaccines.

THE second edition of Dr. GRACE H. GIFFEN DUNDAS'S *Text Book for Junior Nurses*¹⁰ differs from the first which appeared two years ago (see JOURNAL, June 2nd, 1923, p. 933), by the addition of three appendices dealing with subjects included in the State examination for nurses—namely, ductless glands, typhus, malarial fever, and venereal diseases. No mention is made of soft chancres, and the description of syphilis is inadequate but the other additions should add to the usefulness of the book.

A new and cheaper edition of *Golf from Two Sides*,¹¹ by ROGER and JOYCE WETHERED, contains two new chapters in one more unrestrained use of foot work is advocated, in the second the use of a longer swing with iron clubs under certain conditions is admitted as justifiable. Otherwise very few alterations have been made, and the general principles set forth in the first edition, which we reviewed on September 9th 1922 (p. 475), are maintained.

A directory of watering places and health resorts in Germany has been published under the title of *Reichs Bäder Adressbuch*.¹ It contains a detailed account of the various German health resorts in many cases illustrations are supplied, and a suitable amount of detail is provided with regard to hotels, prices, and train services. An index of various morbid conditions is given with a view to directing attention to the places where special treatment may be obtained.

MEDICAL AND SURGICAL APPLIANCES

Jack for Use with Davis Gag

Mr. V. E. NEGLUS, M.S. F.R.C.S. (King's College Hospital) writes: When a Davis gag is used for tonsillectomy it is necessary that someone should support it in order to keep the lower jaw raised and the airway open. This is both tiring and wasteful of energy. Therefore the appliance illustrated has been designed to take the place of the hand of the anesthetist or a assistant. It is a footplate which rests on the patient's chest. It carries on it a rigid upright

rod provided with a rack on one side and a slot on the other. It is a tube sliding up and down on the upright rod and engaging at the top with the gag. It is supported by means of a ring which is a ratchet with a spring it engages with the teeth of the rack and can be freed by an upward pull of the finger. By adjusting the instrument the gag can be supported at any height above the chest between the extremes of four and eight inches. It is an intranasal intratracheal catheter. The instrument is made by Messrs. Mayer and Phelps.

THE HEALTH OF THE NAVY

REPORT FOR THE YEAR 1922

Our statistical report on the health of the Royal Navy for 1922 has just been published. Whatever may be the reason for the belated appearance of these far from voluminous reports, then issue two or three years after the year with which they are concerned detracts considerably from their public interest. But notwithstanding, the delay, they are of value in maintaining a continuity of statistics, by which one year may be compared with another or with the average of a group of years, and the measure of progress in this way gauged. From this point of view the health of the navy in the year 1922 is compared in the report with that of 1921 and with the five year period 1909-13, suitable details for the years 1914-20 not being available.

Incidence of Sickness

The total naval force during 1922 was 96,560. The ratio of admission to hospital for sickness was 559.02 per 1,000, a decrease of 24.35 per 1,000 as compared with 1921 and of 31.1 as compared with the five year period. The average number daily sick in hospital was 2,340.49, or 24.23 per 1,000 representing a slight decrease in both comparisons. This constantly sick rate varied considerably in the different naval stations from 17.49 per 1,000 in the Atlantic Fleet to 30.97 on the China Station and 34 per 1,000 amongst crews on warships to and from foreign stations and imperial personnel lent to the Australian Navy and the New Zealand Division all of whom constitute a group which is designated the Irregular List with a mean strength of 2,670. The constantly sick rates of other stations were 30.4 per 1,000 for Africa, 27.56 and 27.43 respectively for the Home and East India Stations, 22.86 for the Mediterranean, and 20.94 for North America and the West Indies.

The chief cause of inefficiency was venereal diseases which accounted for 10,023 admissions to hospital and 4 deaths. The highest admission ratio for these diseases (282.38 per 1,000) was among men on the China Station and the lowest (79.57) on the Home Station. Other groups of diseases giving high admission rates were injuries 8,931 cases, diseases of the digestive system 7,783 cases and of the respiratory system 6,924 cases. Other groups of diseases accounted for considerably less than 1,000 cases each but influenza as an individual disease, caused 4,514 admissions. The incidence of other individual diseases and specific fevers was comparatively small.

The ratio of invaliding (20.31 per 1,000) was a considerable increase on the average ratio for the five year period especially on the Home Station, where it rose from 24.17 to 34.19 per 1,000 in 1922. The principal causes of invaliding in order of importance, were diseases of the eye and ear, tuberculosis, gonococcal infections, deformities of the limbs, organic disease of the heart, and neurasthenia. The invaliding on account of other diseases or groups of diseases was insignificant in comparison.

Mortality

The deaths during 1922 numbered 333 of which 191 were due to disease and 142 to injuries. The total death rate (3.44) shows a slight increase on the five year period, but a decrease on 1921. The ratio of deaths from disease however, is only 1.97 per 1,000 and is the lowest on record. A table in the report gives the death rates year by year from 1856 onwards. From that year until 1861 the death rates from disease were high, varying from 11.1 in 1856 to 22.0 in 1853. After 1861 a steady decline set in, and from 1895 onwards the death rate from disease was always below 3 per 1,000 in each year except 1915, when it reached 3.48. The year 1922 is the first year in which it has fallen below 2 per 1,000. The death rate from injuries was high on the North America Station in consequence of the drowning of 13 men during the stranding of the *Halcyon* on the coast of Labrador on August 8th 1922. In the table the death rates for 1914 and 1915, the first two years of the war are given as 37.87 and 22.05 per 1,000 respectively, this high death rate being obviously due to battle casualties or other injuries and not to disease. The years 1916-20 are omitted from this table of death rates.

Prophylaxis of Venereal Disease

About two thirds of the report consists of detailed statistical tables of diseases and injuries in each of the stations, at marine headquarters, and in training and dockyard establishments. The text of the report includes short paragraphs amplifying the statistical tables, but gives little or no information.

¹ *Statistical Report on the Health of the Navy for the Year 1922*. H.M. Stationery Office. 1925. (8vo. pp. vi + 15. Price 6s.)

tion case the measures taken to prevent disease, except in the Station, when reference is made to the Sanitary Commission in Constantinople in controlling venereal disease, to the issue of prophylactic outfits, and the provision of ablution chambers on board and on shore. The report states that in practically every instance in which infection occurred prophylaxis was either entirely neglected or employed too late owing to the man being under the influence of alcohol at the time of exposure. As there were 1940 admissions for venereal disease on the Mediterranean Station, instances of neglect to take prophylactic precautions seem to have been fairly numerous in 1922.

Comparative Statistics

The health reports of the Army and Air Force for 1922 have already been noticed but it may be of interest to compare their health statistics with those of the Navy, the following table will serve to show this at a glance.

1922	Navy	Army	Air Force
Admission rate per 1000	559.02	51.80	514.0
Invaliding	20.31	19.31	15.1
Constantly sick	24.23	31.54	21.6
Death	3.44	3.22	4.3

HYGIENE IN SIERRA LLEONE

THE Annual Medical and Sanitary Report from Sierra Leone for the year 1923 contains, besides the usual details of public health and sanitation, a number of special reports. Of these three in particular merit attention. The first deals with beri-beri among prisoners, the second and third with inquiries into the prevalence and transmission in the protectorate of goitre and human schistosomiasis.

Beri-beri among Sedentary Prisoners

The investigation into the health of prisoners in the Freetown Jail, with special reference to the incidence and treatment of beri-beri, was conducted by Dr. W. H. Peacock, Acting Deputy Director of Sanitary Services, Dr. John Y. Wood, medical officer in charge of the prison, and Professor D. B. Blacklock, director of the Sir Alfred Lewis Jones Research Laboratory. It was supplemented by experiments upon fowls carried out by Professor Blacklock with a view to determining the influence on the production of beri-beri of the various constituents of the prison diet.

It was found that in the jail the occupation of tailor predisposes to fatal disease, and in particular to beri-beri. Over a period of ten years the tailors, numbering 15 per cent of the daily average prison population, contributed 33 per cent of the total mortality, while in 1922 they accounted for 57 per cent of the total admissions to hospital on account of beri-beri. The suggestion that these results must be attributed to the sedentary nature of the occupation was confirmed experimentally when fowls kept on a diet deficient in vitamins and deprived of exercise developed polyneuritis and died considerably earlier than controls kept on the same diet but allowed greater facilities for movement. Lack of sunlight did not affect the course of the disease.

Schistosomiasis

Professor Blacklock's inquiries into the prevalence of goitre and of human schistosomiasis covered the hilly Konno and Koranko country and some of the more level districts occupied by the Mende, Temne, and Lamel tribes. The report on schistosomiasis deals in detail with the incidence and effects of rectal and urinary infection in the region examined, and with the identification and biomies of the snails found to act as intermediate hosts. *S. mansoni* appears not to be endemic in these regions, since it was not detected in either faeces or urine, nor were its cercariae included among those harboured by the only planorbis found. On the other hand, a high infection rate with *S. haematobium* obtained in some districts, and its cercariae were found in one of the snails dissected—namely,

Physopsis sp. which is nearly identical to *globosa*. This snail was present in sewage-infected mud wherever the population was infected by schistosomiasis and not elsewhere.

Goitre and Local Contamination

The inquiry into the prevalence of goitre was particularly directed to determining whether it could be accounted for by any natural deficiency of iodine in the water supply. The facts observed support the conclusion that in artificial as opposed to a natural deficiency of iodine is the determining factor in the incidence of goitre, and that this deficiency depends upon infection by faecal organisms or their products, the organisms acting as neutralizers of iodine or inhibitors of iodine absorption. In this connexion it may be noted that the Konnos, who show the highest infection rate, invariably use the water for latrine purposes, while the Korankos, among whom this habit is neither universal nor acknowledged, and who also show a relatively high rate, commonly use the edges of the rivers for defecation. Among the Lambis, Mendes, and Temnes, where the land is used for latrine purposes and the risk of contamination is far less general, little or no infection was found. Among the natives themselves the disease is generally recognized as a Konno disease, and in one Mende village, where the existence of cases of goitre was admitted, it was stated that the sufferers had acquired it at the Konno village of Kuyima, and its prevalence there was accounted for as follows:

'In the old days certain intelligent men observed that the water of a certain stream at Kuyima produced 'big necks' in those who drank it. The intelligent men utilized this knowledge for the purpose of revenge, giving the water to their enemies to drink so that they developed big necks. After a time, however, other people got to know about this property of the water and as a result some of the intelligent men themselves developed big necks. When this stage was reached it was clearly time to take action, so the stream was put out of bounds very strictly. Even to day, however, women who are jealous are in the habit of giving their rivals the water from this stream in palm wine and their victims get big necks so short a period as a week's drinking of the water will produce goitre. Others say that while it is true that the stream was long ago condemned for drinking purposes this was done solely because the stream had become so greatly polluted from use as a latrine that its water was not considered safe.'

It is believed by the majority of natives that—

- (1) Goitre belongs to particular tribal districts or parts of districts.
- (2) Some goitres are hereditary and descend from either parent.
- (3) Goitre is curable by native methods of treatment when small (the method of treatment seen was incisions in the skin over the swelling).
- (4) Once developed fully it never goes away.
- (5) It is not a contagious disease from husband to wife.
- (6) It comes originally from drinking certain waters.

Professor Blacklock found among the chiefs and their advisers, with whom he discussed the object of his investigations as opportunity offered, a lively interest in the problems involved in the progress of sanitary education. The prevailing customs of these people were regarded by the paramount chiefs rather as the result of habit than as immutable rules of conduct. Some of the villages, as explained above, were already prepared to believe in the possibility of infection through faecal contamination of the drinking water, and a keen interest in schistosomiasis was aroused by the collection of snails and the demonstration of the life history of the worm.

In Object Lesson in Hygiene

Regarding education in hygiene as of more radical importance than curative treatment, Professor Blacklock recommends that a "badly sanitized area" of some importance should be selected, put into a state of fairly good sanitation, and so maintained, by way of demonstration. He suggests the village of Kuyima, with a goitre rate of 56 per cent and a schistosomiasis rate of 72 per cent, as specially suitable for the purpose. When the sanitary improvements are finished and the paramount chief has all necessary measures in operation, the chiefs, subchiefs and headmen of the chosen district might be made familiar with this scheme and invited to imitate it in their own villages as soon as possible. The result of such an experiment would obviously be of far more than merely local interest.

LIGHT AND HEALTH

WITHIN recent years the truism that life depends on light has come to possess a more explicit meaning from the broad biological point of view the truth of this statement has been self evident since the discovery of chlorophyll, upon whose energizing behaviour all modern science may have to say of the details of the legend of creation recorded in the first chapter of the book of Genesis, the chronological order of the early events would not be disputed. When the earth was waste and void we read that the business of the first day was the creation of light, and only when this was properly accomplished was it possible for the earth to put forth grass, herb yielding seed, and fruit tree bearing fruit after its kind.

Our own dependence on solar radiation has not, until recent years, been exactly defined, though admitted in principle since the days of Aesculapius. Sunshine has been out of fashion, and in writing of them historians have usually been more interested in the superstitions of sun worship than in the hygienic benefits claimed by their devotees. Thanks chiefly to that high priest of sunlight, Dr. Rolher of Leysin, the health giving properties of light have again attracted the attention of the modern disciples of Aesculapius, who ask why, in the construction of our hospitals and in the treatment of the sick, the influence of sunlight has so long been neglected. The answer to this question is the uniform reply which modern science recites to all empiric claims: it demands a rational explanation and experimental proof. Both of these requisites we now before us, as the unpersuaded would find by reading through the papers submitted to the Sections of Public Medicine and of Therapeutics at the Annual Meeting of the British Medical Association at Bath, published in this JOURNAL last week (pp 470 477) and to day (pp 499 504).

If we begin by reviewing the rational explanation of light therapy, we must admit at once that a completely satisfactory theory of the response of the body to radiation cannot yet be offered, and therefore words must be weighed. The visible rays which form but a small fragment of the solar radiation, have been analysed by physicists and their effect on the retina studied by physiologists and then radiation, have been both infra red and ultra violet, are a new province whose territory has not yet been fully explored. That the rays of longer wave length may be handled with marvellous advantage is proved by the discoveries of radio telegraphy, but the Heitzman waves have no known physiological influence until transformed by special apparatus into auditory waves and the dark infra red rays of benefit chiefly because they warm the surface of the body. It is among the rays of shorter wave length than visible light—the ultra violet rays—that modern research has distinguished the most important health giving agencies and it is therefore necessary to consider how these rays act upon animal tissues.

The ultra violet rays exert no sense organs of the body then existence can only be proved by the effect they produce on the fluorescent screen, photographic

plate, or some similar delicate indicator. They penetrate but little into the tissues of the body, being largely absorbed by the skin, where they cause a local stimulation leading to erythema and succeeded by oedema. The vascular dilatation which follows exposure to these rays is considered to be due to impulses carried from sensory nerves to blood vessels, for, as with other irritants the erythema does not appear if sensory nerves be cut or paralysed. The action is therefore not a direct action on the blood vessels, it is not even a direct action on the skin but after a latent period follows on the chemical molecular changes in the cells induced by alteration in the electrical charge of the ultramicroscopic particles of the colloidal protoplasm. This stimulation of the surface of the body produces reflexly, through the medulla, a slight increase in metabolism, the absorption of oxygen the output of carbon dioxide, and nitrogenous excretion are all improved and the general minimum is raised. Deposition of pigment recomposes these changes, none of which, however, are peculiar to light for they are met with as the result of other forms of stimulation. We must look more closely to understand the specific action of light on which radiotherapy is based, but here we shall have to be content with a tribulation of the subtler changes wrought by the ultra violet radiation which laboratory experiment has hitherto discovered without attempting to fit these together into anything more than a working hypothesis.

One of the first peculiarities of ultra violet radiation to be noticed was its lethal effect on living cells. Lowly forms of life, such as infusoria and bacteria, are very sensitive to this radiation—an observation which led to the view formerly held that success in the treatment of lupus by radiation depended partly on the destruction of tubercle bacilli within the skin. From the bacteriological point of view another important observation was that radiation of the skin results in an increase in the haemo bactericidal power of the blood as tested *in vitro*. But it is in the province of biochemistry that the most remarkable results of radiation have been observed. The discovery of the influence which ultra violet light exerts on the storage of calcium and phosphorus and then equilibrium both in growing and mature animals has played a very important part in unravelling the pathology of rickets, and has pointed the way to treatment. Finally, the observation that previously inactive foods may be given nutritive properties by preliminary radiation must be added to the list. Professor W. E. Dixon, in his paper printed this week, points out that it is generally believed that foods possess nutritive properties by virtue of their cholesterol content. The cholesterol becomes active after radiation but too long an exposure of cholesterol or of substances containing it, results in their becoming inert is a remedy for rickets.

Turning from the theoretical basis of light therapy to the experimental proof of its efficacy, we find substantial support from many different quarters. The two sectional meetings at Bath are of special value because they recount the experience of experimenters in different branches of medicine, and because of the practical considerations with which they deal. The experimental proof of the value of light therapy is based on many years experience, and no one can read through these six articles without being struck by the remarkable unanimity with which they testify to the value of ultra violet ray therapy in lupus rickets, and surgical tuberculosis. We meet with several observations also which invite speculation on

the possibilities which the future may unfold for instance Dr C E M Jones's account of the mental tests performed on physically defective children in London and patients at Alton which showed that the children at Alton were mentally nearly a year in advance of the London children. Sir Henry Gray's suggestion that ultra violet light might improve the nutrition of the grey matter of the brain, as it induces bone repair in the case of rickets, needs careful study, though many other reasons suggest themselves for the mental superiority of children living in the open air. Again, the remarkable discovery that inactive food of certain kinds can be made antinutritive by radiation may lead to the introduction of valuable new methods for feeding debile infants.

Now that the public as well as the medical profession are awake to the benefits of light therapy, there is a considerable danger that exaggerated claims will be made for sunshine treatment and ultra violet ray appliances, and that these new methods may be to some extent discredited because of their unskilful or inappropriate use. We have recently called attention to the dangers of ultra violet light baths (*British Medical Journal*, April 11th, 1925, p. 708), and several letters have appeared this year in our columns indicating the serious consequences that follow an unduly prolonged exposure in patients taking "light baths" without medical advice. It must be remembered that in unsuitable cases light treatment will produce depression and not stimulation, and the same may follow overdosage. A possible explanation for this may be found in the fact that an overdose of light will produce a rise in the haemo-brafericidal power of the blood which later may fall below normal and remain sub-normal for some time before gradually rising again. It is fitting therefore, to end this brief survey of the merits of light therapy with a word of caution.

LONDON'S WATER SUPPLY.

SIR ALEXANDER Houstoun's report on London's water for the year which ended March 31st 1925 (the nineteenth of the series), has now been issued. It runs to about 120 foolscap pages in addition to numerous diagrams and photographs. Much thought and care have been devoted to the scheme of the report, the author having evidently been anxious to make it useful and attractive not merely to those who are acquainted with his previous eighteen years' records, but to new readers without knowledge of what has gone before. Having this in view, he begins with an introduction in which he conveniently quotes from an American writer a good summary of the first fifteen years' work for the Metropolitan Water Board, followed by a brief account of the main sections of his eighteenth report. Next, for the reader's benefit he gives a synopsis of the matters dealt with in each one of the seventeen sections constituting the present volume, the synopsis being not merely a table of contents, but a reasonably complete condensation of what is to follow throughout the report.

Chlorination again receives much attention, in respect both of the Thames water and of the New River water. As regards the former the need for pumping into the Thames aqueduct of turbid subsoil water from a deep trench required for construction of a great concrete conduit alongside the aqueduct, gave rise to much anxiety, but chlorination was successful in preventing harmful results. In the New River heavy winter rains deteriorated the water, but here

also chlorination was efficient. Avoidance of objectionable taste in the water so treated is always attended to by means of careful dosage and the use of permanganate. In the New River the work has been carried on for six consecutive years without giving rise to taste troubles. Sir Alexander Houstoun directs attention to chemical investigations by Mr B A Adams regarding this question of the taste of chlorinated drinking water. He found that atmo-spheric pollution adversely affected chlorinated water through absorption of apparently phenoloid gases by the water in iodiform taste being the result, as in a case where air polluted by the emanations from a city gasworks had opportunity of affecting a water supply. Mr Adams observed that the reaction does not take place when the water contains a trace of ammonia and he advises that a chlorinated water should not be mixed with water which has been so exposed. As regards the value of permanganate it is stated that doses of from 0.5 to 1 per million not only prevent development of taste in chlorinated waters but aid in sterilization. The cost of permanganate, however, is more than three times that of chlorine.

The great new reservoir at Latchford, recently opened by the King, will when completed double the present storage capacity for Thames water. The value of storage not merely in providing a supply to tide over times of exceptional drought but as an important means of purification, is now universally recognized, largely in consequence of Sir Alexander Houstoun's own work during the twenty years he has been Director of Water Examinations to the Metropolitan Water Board. Filtration however is also essential and the present report gives in account of further experiments which have been made in rapid filtration, is a preliminary to slow sand filtration. The Director believes in the expediency of primarily rapid filters working at the rate of 100 to 200 gallons per square foot per hour, as a preliminary to slow sand filtration which under these conditions may be operated at two or three or more times its normal rate with the addition of chlorination as an integral part of the process.

It is good that an official should be in idealist which is quite different from being a fiddler and Sir Alexander Houstoun's ideal is to see the Thames become a salmon river again. He reverts to this question in the present report, and points out with regard to the amount of dissolved oxygen, that at Hampton the water is well aerated. The lowest figure in the year was 0.77 part per 100,000 on June 7th and 19th, that amount being well above what is necessary for fish life. In times of flooding and when tidal is mixed with river water, the greater volume of water would more than make up for any slight deficiency of oxygen. The difficulty is the pollution and deoxygenation of the tidal part of the Thames by great quantities of treated sewage effluent from the Barking outfall. Summing up his views on the matter he writes: "If it were possible, even temporarily, to purify the tidal portion of the Thames during the descent of the smolts and ascent of the salmon there is nothing in the state of the upper river to render salmon life impracticable and, further, assuming the possibility of this ideal ever being fulfilled, the habits and instincts of the salmon tribe are such that the introduction of their ova into the upper Thames would lead to the chain of events being visualized."

Having called attention to the Director's ideal, we do not follow him further in his valuable report, but conclude by expressing the hope that he may be able to embody in some future record the story of the realization of his dream of the Thames as a salmon river.

THE GOVERNMENT LABORATORY

THE report of the Government Chemist, Sir Robert Robertson, K B E, D Sc, F R S, upon the work of the Government Laboratory for the year ending March 31st, 1925, has just been issued. The chemical work of some eighteen Government departments is carried out for the most part in the laboratories at Clement's Inn Passage, in the Customs House laboratory, or in a number of chemical stations at the principal seaports, where certain classes of samples are tested by Customs and Excise officers trained for this purpose. Further, the department maintains a laboratory in the Geological Survey museum for the analysis of ores, and carries out all the inspection of food stores and supplies for the War Office at a laboratory in Deptford. The work of the head laboratories and of the chemical stations has increased very much in recent times. In all, the number of samples examined last year was more than 448,000, as compared with fewer than 390,500 in the preceding twelve months. The work undertaken for the Ministry of Agriculture and Fisheries includes analysis of dairy produce and margarine, and the investigation from time to time of samples of river water and effluents to ascertain the effects of certain types of water pollution on fish and fish food. Much of the great volume of work for the Board of Customs and Excise consists in the testing of samples, in connexion either with the assessment of duty and drawback or with the regulations and licences governing the manufacture and sale of dutiable articles. As many as 54,398 samples were examined for the purpose of assessing the duty on beer, and 1,257 samples of brewing materials were examined for arsenic, of which 90 were found to contain this in slight excess of the limit laid down by the Royal Commission on Arsenical Poisoning. Of 113 samples examined for the presence of morphine, diacetylmorphine, cocaine, and eugonine, 22 were found to contravene the provisions of the Dangerous Drugs Act, 1920. One of the duties of the department is to examine and report on applications to the Commissioners of Customs and Excise for rebates on alcohol used in making medicinal preparations or for scientific purposes, and for permission to receive duty-free alcohol for use in manufacture, terehling, or research. The fact is noted that pyridine has been adopted as an additional denaturant for mixing with methylated spirit in order to make it undrinkable, but we find no reference in this report to the valid objections raised by the medical and pharmaceutical professions against the use of pyridine in spirit employed for surgical and kindred purposes. More than 116,500 samples of wine were examined for the purpose of rating their alcoholic strength, these included 20 medicated wines, and of 58 grape juice samples 22 were found to be dutiable as wine. On behalf of the Ministry of Health a few pathological specimens were tested for poisons in connexion with investigations into suspected cases of poisoning, 30 samples of medical preparations (mainly smuggled morphine and heroin) were submitted by the Home Office, 120 samples of liquors, foods, and drugs were tested for the police authorities with a view to proceedings in the courts, and the Director of Public Prosecutions sent a number of samples (mainly of articles relating to charges of murder) for examination of blood stains. The examination was continued of such materials as lead glazes, crucibles, and prints, for the purpose of inquiries affecting the health of factory workers. For the India Office 32 samples of anesthetics were tested as to their conformity with specification, hospital supplies were examined for the Ministry of Pensions, and waters and disinfectants were submitted by the Government of Northern Ireland for report as to their suitability for domestic and other

purposes. On behalf of the Post Office the Government Laboratory watches over the purity of the materials used in mailing stamps, while for the Board of Trade it tests the lime juice and lemon juice for ewers on ships at sea and approves the disinfectants for emigrant vessels. The manifold activities of the department include recovery of iodium from accumulated stocks of disused luminous compass dials and gunsights, and investigation of the decay and disintegration of stone in town atmospheres. In a list of papers read by members of the Laboratory at periodical staff meetings we note communications on miasm by Mr W Smith, on sewage and effluent disposal by Mr H Stephenson, and on the bacteriology of water by Mr R M Mooney. The routine work of the staff is no doubt often tedious, but now and then there seem to be brighter moments. They may, for instance, be invited to settle the question whether a wine is still or sparkling, or a broken flask from a ceiling at Hampton Court, sent by the Office of Works, may inspire them to reconstruct the way in which the painter did his work in the seventeenth century, or, again, they may be asked to say whether the proportion of alkalis in a fragment of Roman plaster or mediæval mortar was the cause of its durability.

CLEAN MILK EXPERIMENTS IN WESTERN AUSTRALIA

At the beginning of this year a Royal Commission was appointed in the State of Western Australia to investigate and report on the metropolitan milk supply. The Commission has issued recently an addendum to its report, containing a survey of the quality of milk from different sources and handled in various ways. The samples of milk were taken before and after cooling, at the dairy farm, on arrival at Perth station, and on delivery to the consumer, at hand milking and at machine-milking dairies, from herds and from single cows, under ordinary and under specially clean conditions. The method of testing was by plate culture, counts being made of the total bacterial content and of the numbers of *Bacillus coli*. Counts of *B. coli* were made by cultivation from 0.5 c.c. of undiluted milk in a plate of MacConkey bile-sugar-lactose agar medium. It is satisfactory to note that the results of the experiments confirm generally the opinion expressed in the discussion in the Section of Medical Sociology at Bath,¹ that reasonably clean milk can be produced without the expenditure of much time, money, or trouble. Thus one of the conclusions arrived at by the Commission is that "the use of milking machines under existing conditions gives very unsatisfactory results." Milking machines under very good conditions give no better results than those obtained by hand milking under ordinary conditions. Under the best conditions the results of machine milking do not approximate to those of hand milking, owing to the difficulty of proper cleansing and maintenance of the machine. In the opinion of the Commission the most important factor in the production of clean milk is the sterilization of all utensils. This can be done by dipping in boiling water immediately before use. The chief expense is the provision of a rectangular boiler capable of taking a milk churn or drum laid on its side. The next precaution of importance appears to be the wiping of the cow's udders with a damp cloth. Special buckets and overalls for the milkers seem to be comparatively unnecessary. The Commission summarizes the precautions as "reasonable cleanliness on the part of the milker, washing of the udders, rejection of first jets, scalding of all utensils, and the use of ice tubes in milk which had to be stored overnight." Even under existing conditions country milk arriving at Perth station from hand milking dairies gave a relatively low bacterial count. By the time it reached the consumer the count

WELFARE OF THE BLIND

was high. With the simple precautions enumerated the Commission found that hand-milking dairies could produce milk of an extremely satisfactory degree of cleanliness, and deliver it to the consumer in the same condition.

THE WELFARE OF THE BLIND

The annual report for 1923-24 of the Advisory Committee of the Ministry of Health on the Welfare of the Blind states that 10,625 blind persons between the ages of 50 and 70 years are in receipt of old age pensions, as compared with 9,921 the previous year. The total is 85 per cent of those eligible. Some hardship occurs in a few cases owing to blind persons having private means just too much for them to receive a pension, and the committee recommends some easing of the regulation. It does not, however, recommend the total abolition of the income limit, nor support the suggestion that all adult blind persons should receive a pension of 10s a week, holding that this would reduce efforts for good education and industrial success. A great increase in schemes made by local authorities for the blind is evidenced by expenditure. This was £14,671 in 1921-22, and is £90,452 for 1924-25, with corresponding grants from the Ministry. The greatest part of this expenditure is on workshops and home workers—that is to say, it is industrial. Efforts have been made to increase the number of handicrafts suitable for the blind, but it is found that with the possible exception of stringing tennis rackets, no new industries can be introduced. The register of the blind shows 36,518 persons in June, 1923, as compared with 25,840 in 1919. The increase is mainly due to better ascertainment. At the present time 56 per cent are over 50 years of age, as compared with 52 per cent in 1921. The committee draws attention to the bad practice followed by some education authorities of placing myopic children in schools for the blind. We understand that the Board of Education is pressing for the provision of special accommodation for myopes. An appendix contains an analysis of occupations of employed blind. The greatest single group is that of the basket makers, thereafter come knitters, dealers (tea agents, etc.), mat makers, brush makers, and musicians.

JUVENILE EMPLOYMENT

On every side is heard the remark, ever increasing in insistency, that a huge waste of human material takes place because not enough effort is made to sort out workers, particularly while young, into the occupations for which they are most fitted. Those trends of thought are reflecting on our social work among adolescents, and to meet the demand more and more paid and voluntary workers are being drawn in through children's civic committees now established in connexion with every elementary school. Mr Bolton King, in his book entitled *The Employment and Welfare of Juveniles*,¹ gives an account of these committees, how they came into being, and how they seek to co-ordinate the known capacities of the children to work that is available, and of the successes which have attended these efforts. Committees were first formed in London in 1907, for schools definitely classed as "necessitous," with the object of carrying out the provisions of the 1906 Act for the feeding of school children. Two years later the system was extended in a modified form to all elementary schools within the area. They were to cease to be merely feeding committees, and to become "Care" Committees, taking an interest in the general welfare of children and co-operating with the parents and existing organizations

As voluntary social workers have seen one sphere of usefulness after another absorbed into the State machine, new outlets have been discovered, and in the Care Committees they have come into their own, for, as Mr King shows, for much of this kind of work volunteer effort is welcomed by local and central authorities as essential to the efficiency of the public system. To the school doctor the Care Committee is indeed invaluable. Through the offices of its members he is able to see that necessary medical treatment is efficiently carried out, to obtain improved home conditions for the child, and to arrange for convalescent treatment and holiday trips, for the difficult case of physically defective children he can secure an efficient and kindly interest in the provision of suitable work when the child leaves school, without which he knows that all or nearly all the patient effort of years of school training is likely to be lost. What is true for a few of the school children is also true for the many, the Care Committees are greatly valued by parents of the normal children as a means of getting information they cannot obtain unaided. Mr King deals with the development of these committees, the scope of their work and how they do it, with choice of employment, continued education, and apprenticeship, the duties of the social worker, and the law relating to the industrial adolescent. In three appendices he gives particulars of unemployment insurance, and an alphabetical index of for certain occupations, and an alphabetical index of common trades and their requirements. Each order of industrial work or job is tersely described, and accounts are given of methods of entry, of prospects and pay, and qualifications, educational courses are indicated, and some warnings. For example, it is said: "Messenger work has a strong appeal to boys who leave school. It leads nowhere, and boys, when they reach the age of 17, are almost invariably dismissed without any training for another occupation. Parents are strongly advised to keep their sons clear of this occupation, either under a private company or local or central government, except under the Post Office." Mr King's book will be very useful to every school worker, and no school doctor can afford to be without the information he has collected.

THE HEALTH OF GIBRALTAR

The inhabitants of Gibraltar continue to enjoy remarkable good health, in spite of the high proportion of one room dwellings and generally overcrowded state of the city. According to the report for 1924,¹ by Lieut Colonel W. C. Smales, R.A.M.C., the medical officer of health, the death rate was 14.66 per 1,000 of fixed civil population, as compared with 17.6, the average for the preceding ten years. When corrected, however, for age and sex distribution for purposes of comparison with British towns, the standard death rate becomes 17.25 per 1,000. The infantile mortality fell to 91.6 per 1,000 births, or 17.0 per 1,000 below the rate for 1923. But this is not the lowest on record, for it was only 70 per 1,000 in 1909, and 75 in 1912 and 1913. The zymotic death rate was 1.05 per 1,000, and for pulmonary tuberculosis 1.5. The birth rate was 22.5. These rates have not varied much in recent years. Colonel Smales's report contains an interesting chart of small-pox epidemics in Gibraltar between 1871 and 1924. In several of these epidemics, especially those of 1871-73, 1878-80, and 1896-98, small-pox occurred in three successive exacerbations covering a period of two to three years before it eventually disappeared, a characteristic which was noted in the report for 1896, when a similar chart was published. The report for 1924 does not differ materially from its predecessors in general contents, but by the inclusion of small-pox and other charts it is somewhat more voluminous.

¹ Annual Report on the Health of Gibraltar for the Year 1924. Gibraltar: Garrison Library Printing Establishment. 1925. 12s. 6d. pp. x + 74. 4 charts and 1 plan.

and there is added an excellent plan of Gibraltar. It also contains an elaborate table giving details of school accommodation and a significant squared table showing the distribution of families of one to six and over six members in one to six and over six-room dwellings. As many as 1,316 out of a total of 3,480 families occupied one room only. Owing to building and other restrictions, the fixed civil population has remained stationary between 16,000 and 17,000 for a long succession of years. The sanitary administration until recently was in the hands of sanitary commissioners. There is now a city council with a public health department, but vaccination, civil hospitals, and inspection of schools and food are administered by a colonial department, and sanitary matters connected with the port by a board of health. Under these three departments sanitary activity and sanitary administration and personnel have greatly expanded, and, if one may judge by the facts recorded in the medical officer of health's annual reports, little is left undone in the application of preventive measures against disease.

THE FRENCH RIVIERA

In a recent number of *La Presse Thermale et Climatique* Dr. Gaston Sardou sets forth his views on the value of the health resorts of the French Riviera for the treatment of various pathological conditions. His attitude is that of an impartial observer, and not that of the enthusiastic bath physician, who is apt to vaunt the merits of his own particular spa and to deny that it can possibly do anything but good to any visitor. After briefly describing the physical geography, or what Huxley called the physiography, of the Côte-d'Azur, and the effects of the various winds on temperature and moisture, he states that the nature of the marine and alpine constituents of the climate varies according to the position of the particular place in question. The influence of the moist east winds diminishes, while that of the mistral, which is a north-westerly wind, increases, as we go from east to west. Moreover, purely local features affect the climate of particular places. Dr. D. W. Samways of Mentone has contended¹ that the characteristics of the Riviera climate are more those of a mountain than a marine one, since the prevalent winds are northerly, but with the exception of the mistral they are not cold in winter, because they have been warmed by passing over the sun-warmed surface of the land. Wet and cloudy weather is nearly always associated with south-easterly or south-westerly winds. In the paper referred to, which was read at a meeting of the Medical Society of the Mediterranean Littoral held at Nice, Dr. Samways entered into a very full exposition of the meteorology of the Riviera, which is well worth reading. Dr. Sardou would sum up the effect of the climate in general by attributing the greater part of it to stimulation, much of which may be a result of the blue or ultra-violet rays of the sun, to which so much lay as well as medical attention is just now directed. In this connexion it would be interesting to attempt to explain how it came about that ever since the decay of the Roman empire the inhabitants of northern lands, deprived to a large extent of the beneficent ultra-violet rays, have prevailed so often and so signally over the fortunate dwellers of the sunny south. Has the black man, for instance, defended himself by means of his pigment only too completely from the sun's rays, and thus lost all the benign influence which might have developed his intelligence and his pushfulness? Dr. Sardou does not go into this somewhat obscure speculation, but he expresses the opinion that the action of the sun's rays is curative in many conditions, especially when accompanied by heat. To sum up, the climate of the Riviera acts by heliotherapy,

reiotherapy, psychotherapy, myotherapy, thalassotherapy, physiotherapy, and barometric pressure. But although so beneficial in all depressed conditions of the organism, the climate is unfavourable for diseases characterized by hyperaesthesia and hyperfunction, such as chronic fever, phthisis, cachexia, and states of bodily or mental excitement. Lastly, the effects on the mind of the visitor from the north of the bright skies, clear air, and charming scenery are not the least among the curative agencies of the Provençal littoral, and the more the visitor sees of them and the less he has to do with the germ-laden atmosphere of casinos and other places of public entertainment the better it will be for his bodily health and his financial wealth.

SKIN TUBERCULOSIS IN CATTLE.

INVESTIGATIONS into the control of bovine tuberculosis have brought to light many new facts, and one of the most interesting among them is the existence of tuberculous lesions of the skin in cattle. Carpenter and Goldberger¹ report that an increasing number of specimens of this type have been encountered. In every case, however, the inoculation of guinea-pigs was negative. Calmette (1923) divides tuberculous lesions of the skin into four classes—lupus, ulcers, granoma, and lymphangitis. All these have been found in cattle, but those found by Carpenter and Goldberger were all of the lupus type. Calmette has already observed that bacilli in the lupus tissue are generally benign on inoculation, and to this he ascribed the fact that lupus cannot be inoculated from one human being to another. He regarded it as a rare condition in cattle, but the present series of cases indicates that it is by no means so rare as had been supposed. The condition generally develops from some traumatic lesion, usually of the extremities, and is commonest in young animals. The lesions are histologically the same as those in man, and the bacilli are considerably attenuated. In this the tubercle bacillus follows a general rule, which is exemplified also in the bacillus of anthrax and the virus of pleuropneumonia in cattle. Carpenter and Goldberger have been able to reproduce the disease experimentally in cattle, and to show that lupus will cause the animal to react to the tuberculin test in a manner similar to tuberculosis in other organs.

THE MEDICAL REGISTER UNTRACEABLE PRACTITIONERS

We publish in the SUPPLEMENT this week, at the request of the Registrar of the General Medical Council, a list of the names of those medical practitioners who have not replied to his inquiries as to the accuracy of their postal addresses. Any practitioner who finds his or her name included in this list should communicate at once with the Registrar of the General Medical Council, 44, Hallam Street, Portland Place, London, W 1.

¹ Cornell Veterinarian 19.5 xi pp 1-8 1923

The first social evening of the session at the Royal Society of Medicine will be held at 1, Wimpole Street, W., on Tuesday, October 27th.

The eleventh Norman Kerr Memorial Lecture before the Society for the Study of Inebriety will be delivered by Dr. R. Herod of Lyons on Tuesday, October 15th at 4 p.m., in the hall of the Medical Society of London, 11 Chandos Street, Cavendish Square, W 1. The subject of the lecture will be alcoholism as an international problem. A luncheon is to be held at the Welbeck Palace Hotel at 1.30 p.m., in order to provide an opportunity for meeting Dr. Herod. The president, Sir William Wilcox, will preside at the luncheon as well as at the lecture.

SOME ACHIEVEMENTS OF INDUSTRIAL LEGISLATION AND HYGIENE*

BY

SIR THOMAS OLIVER, M.D.,

NEWCASTLE UPON TYNE,

PRESIDENT OF THE BRITISH SECTION CONGRESS OF INDUSTRIAL HYGIENE

INDUSTRIAL hygiene is a comparatively recent branch of medicine. Although Ramazzini published his treatise on *Occupation Diseases* in 1700, it was the utilization of steam as a motive power which stimulated the growth of modern industry. The manufacture of pottery, also of bricks for building purposes, is one of the oldest trades. Coal mining, on the other hand, is one of the most important industries, as it is one of the most dangerous.

Coal Mining

The Romans during their occupation of Great Britain made use of the coal obtained from drifts in the city and neighbourhood of Newcastle upon Tyne. There was no deep mining for coal in those days. It was in the early part of the thirteenth century that permission was granted by Henry II to dig for coal in the North of England. During the early part of last century coal mining in Great Britain was a procedure attended by great hardships, physical and social, upon those who followed the vocation. A hundred years ago the hours of work were long—twelve to thirteen a day, boy labour was exploited and female labour underground was utilized, there was only one shaft leading into the mine, which served both for men and material, and as a consequence not only was there no through ventilation of coal mines, but in the event of the single shaft becoming blocked there was no escape for the men underground or means of their comrades above ground reaching them. It was the occurrence of such an accident at a pit a few miles from Newcastle, and known as the Hartley Colliery disaster, sixty years ago or thereabouts, which led to the compulsory provision of two shafts into a mine, and which led to the through ventilation in use to-day.

Two months ago I was called professionally to see a retired coal miner 72 years of age who told me that he began work in the mine at the age of 9 years, that he worked from 4 a.m. till 5 p.m. and for thus thirteen hours would a day he received 10d. He had to be wakened at 3 a.m. left the house at 3.50 a.m. and had to walk more than a mile to the mine where at the pit head he was obliged to be ready to descend at 4 o'clock in the morning. He often slept while he walked to and from his work and like the boys younger than himself employed in the mine he frequently fell asleep at his work and was ill treated for this by the foreman. In the winter months collier boys never saw daylight except on Sunday.

It is impossible to say what the number of fatal accidents was three quarters of a century ago, for statistics at that period were not kept, but the death roll was heavy. Before 1814 it was not the custom for inquests to be held on colliers who met their death by an accident in the mine. As showing the death rate from mine accidents during the latter half of last century, the following data supplied to me by Professor Louis of the Mining Department, Armstrong College, are of interest. Taking quinquennial periods, the death rates from mining accidents per 1,000 men employed underground in Great Britain were—

1851-55	5.149	1876-80	2.709
1856-60	4.628	1881-85	2.312
1861-65	3.791	1886-90	2.042
1866-70	3.995	1891-95	1.704
1871-75	2.736	1896-99	1.479

If we take two later decennial periods for comparison, we find that the average annual deaths from accidents in British mines due to all causes were, from 1873 to 1882, per 1,000 men employed, 2.5, and from 1911 to 1920 1.3. With the exception of the United States of America the statistics of other countries also show a decline in the accident fatality rates. In Germany the rate, which was 3.18 per 1,000 men employed in 1879, had fallen to 2.40 in 1914, in the United States the fatal accident rate had risen from 3.5 per 1,000 in 1890 to 3.62 in 1920, while during 1920 the rate for Belgium was 1.13, for France 0.77, for Great Britain 0.88, and for Germany 2.40. Coal mining in the United States is a comparatively modern industry, the men

have not been so long trained as those in the older countries. In addition many foreigners are employed, and, as a consequence of difficulties incidental to language, orders given by officials may not be readily understood. The men, too, in order to make high wages, work harder than in most countries. If the accident rate is measured by the number of men killed for every million tons of coal raised, the figure for the United States compares most favourably with those of other countries.

Spreading generally for all countries, but especially for Russia, the figures show that improvement has taken place in the reduction of fatal accidents in coal mining largely consequent upon freer ventilation, distillation of the mine for gas before the men descend, greater use of safety lamps, substitution of the higher explosives for ordinary black gunpowder, also the employment of skilled men to place in situ the cartridges and fire them.

Although one of the most dangerous of occupations, coal mining in Great Britain remained free from protective legislation until 1842, when, owing to the serious condition of affairs revealed by a Royal Commission, women and girls were excluded from working underground. It was not, however, until thirteen years afterwards that measures were introduced to protect the health, life, and limbs of the workers. For the saving of life in coal mines we are indebted to the attention given to the subject by men engaged in chemical and physical research. The employment of the 'safety lamp' recommended by Sir Humphry Davy has prevented many explosions, just as the daily inspection by trained men of the mines at the working face of the mine before commencing to haul coal has been the means of saving many a miner from becoming a cad. One other important circumstance has added considerably to the safety of the miner's vocation. Three quarters of a century ago the dangers of explosive gases in coal mines had been recognized but it was not until a few more decades had passed that Professor Gilloway and Mr. H. Hall showed that as widespread explosions frequently followed the firing of cartridges in mines some of these explosions were due to the dry coal dust which was raised into the atmosphere, catching fire, and travelling with explosive rapidity through the underground passages. Men were thus killed partly by gas, partly by burns, and in other instances, where death was not immediate, by pneumonia. Coal mining on a large scale in France, Belgium, and Germany is of recent date compared with that of Great Britain. It was not, for example, until 1766 that coal mining in Westphalia became a prominent industry. Other coal producing countries have profited by the experience, the mistakes, and the failures of British mining methods.

As an illustration of how hygiene measures introduced to protect the workers in one direction may inadvertently lead to disaster in another I cannot do better than reproduce the experience of the German mining authorities in the Ruhr a few years ago. Before this was several of the coal mines in Central and Western Europe had become infected by ankylostomiasis. I visited the Belgian, German and Hungarian coalfields and I descended into the Lothringen mine near Bochum. I was much impressed by the excellent organization of the sanitary measures which had been carefully prepared by Dr. Tscholtz and the adequate hospital provision made by the mine authorities for combating the disease in Westphalia. Although the parasite had gained entrance into the two mines of Coinwall, British coal mines fortunately remained free. Ankylostomiasis and have acquired heat and a considerable amount of moisture for their development. A few years previous to my visit to Westphalia there had occurred explosions in the German coal mines for which high temperatures and the dry coal dust were partly believed to be responsible. With the view of reducing such risks it was decided to introduce water spraying into the mines. This however only caused fresh trouble for the mine became infected by the ankylostoma parasite which it was believed had been brought thither by Polish and Italian workmen, also probably by some of their own miners who during the summer months had worked in the brickfields around Cologne and elsewhere. At any rate in 1900 water spraying of mines became general and the result was as follows. Cases of ankylostomiasis numbered 107 in 1896, 113 in 1897, 99 in 1898, 275 in 1899, 1,030 in 1901 and 1,355 in 1902. The rapid and great increase in the number of cases of ankylostomiasis after water spraying can hardly be regarded as a coincidence.

As a class, coal miners suffer less from pulmonary tuberculosis than most men employed in dusty occupations, but, as Professor Collis remarks, 'low as their phthisis mortality is, the experience for coal miners displays certain statistical characteristics which are distinctive of dust phthisis, and these are (1) an unusually late age of maximum incidence, and (2) an association with high mortalities from other respiratory diseases. Miners who are working at the coal face suffer from phthisis rather more than other miners below ground and

* Address (abridged) delivered before a plenary session of the Congress of Industrial Hygiene, Amsterdam, September 12th 1924.

workers above ground Phthisis in coal miners commences to express itself at and after 35 years of age

Periods	Age period—	35	45	55	65 and over
1890-92	1.45	2.07	2.23	2.03	
1900-02	1.03	1.52	2.04	1.47	
1910-12	1.02	1.31	1.43	1.02	

Thus shows the improvement which has taken place in the mortality rate of coal miners from phthisis

Manufacture of Lucifer Matches

There must be many in this audience who, like myself, twenty to thirty years ago, were witnesses of the ill health experienced by men and women who worked in match factories wherein white phosphorus was used. The men who dipped the matches in the phosphorus paste, and the women who filled the boxes, frequently suffered from necrosis of the jaw bones or died from septic meningitis or bronchopneumonia. In other instances where the poisoning was less severe the workers suffered from gastric trouble, anemia, and albuminuria, or from a tendency of the long bones to become fractured owing to peculiar fragility of the bones. So great were the sufferings of the persons affected that it became imperative that some united action should be taken by various countries to produce matches which would strike anywhere without, in their manufacture, the workers incurring risk to their health. As far back as 1879 Switzerland introduced a bill to prohibit the use of white phosphorus. In 1899 the British Government invited Sir Edward Thorpe, Dr Cunningham, and myself to visit match works at home and abroad with the view of ascertaining how the workers might be protected against the risks they were exposed to. Like many of our Continental confreres, we were of the opinion that the time had come when a harmless substitute should be found for the dangerous white phosphorus. It was Lorinser of Vienna who, in 1845, first drew attention to necrosis of the jaw bones as an occupational disease, but in every country in which lucifer matches had been made from white phosphorus there had occurred cases of phossy jaw. Chemists vied with each other to find a safe substitute for the dangerous metalloid. To French scientists fell the honour of showing how, by employing phosphorus sesquisulphide, lucifer matches could be made without risk to the health of the workers. After a congress of the various Governments, held in Berne in 1906, the match producing countries of Western Europe decided to manufacture lucifer matches by the safe method and so successful has been the result that the occupation is now free from the risks of three decades ago. Phosphorus necrosis has disappeared.

Manufacture of Mirrors

Chemical research has also proved helpful in other trades. It is not so long ago since quicksilver was used in the manufacture of mirrors. Many of the men then employed suffered from mercurial poisoning. Apart from the unhealthy conditions set up in the month, through vaporization of quicksilver, the workers became the victims of muscular tremor and occasionally of paralysis. Since making use of silver nitrate preparations the men have had good health, and the industry is now regarded as a healthy one.

Arsenical Pigments

Just over twenty years ago I was a member of the Dangerous Trades Committee of the Home Office to which was given the task of investigating several trades which were regarded as inimical to health. One of these was the manufacture and use of wallpapers which contained arsenic also the manufacture, mixing, and use of emerald green. It had been found that illness hitherto unrecognized was the result of sleeping in bedrooms the walls of which had been covered by paper containing arsenical pigment. Men employed in the grinding and mixing of such colours suffered from ulcers on their hands and fingers and upon the genitalia. In other instances a painful neuritis was established, which occasionally ended in paralysis. In the United States, in Holland, and other countries, the subject had also received attention. In Massachusetts, for example, a law had been passed in 1900 limiting the amount of arsenic in wallpaper to the extent of 0.1 gram per square yard, but at the time of the British inquiry alluded to we found manufacturers had been placing several grams in a square foot of wallpaper. The use of arsenical pigments in wallpaper

in Great Britain was subsequently prohibited then plies being taken by uniline and other safe colours. To the fortunate results which have followed in all the trades wherein arsenical compounds are used, stringent regulations, improved ventilation, and the employment of means for the removal of dust have contributed.

Carbon Bisulphide

Thirty years ago in the manufacture of india rubber goods in Great Britain there was much serious illness among the men and women employed in the factories. The illness was traced to the use of carbon bisulphide as a solvent for sulphur monochloride in the vulcanization of rubber. The vapour of bisulphide when inhaled causes intoxication not unlike that which follows the drinking to excess of alcoholic liquors. In the milder forms there are headache, vomiting and a staggering gait, in the more pronounced form the symptoms, while primarily of the nature of aggravated hysteria, occasionally become those met with in acute mania. In other instances, again, there are indications of peripheral neuritis followed by paralysis of the limbs. Since new methods of vulcanizing rubber by means of the incorporation of flowers of sulphur in a closed chamber under the influence of heat have been introduced, the trade has become healthier, and there are no longer the distressing and crippling forms of illness which attacked the workers less than half a century ago.

Lead and its Compounds

If there is one metal more than others which, since the rise of the modern industries, has exacted in all manufacturing countries a high toll of human life, it is lead and its compounds. One thing characteristic of industrial lead poisoning is the insidious manner in which it may develop, ill health may gradually steal over the workers, while, on the other hand, symptoms rapidly show themselves—as, for example, by the sudden onset of acute abdominal pain, or there occurs loss of power in one or both hands between night and morning. As lead and its compounds are used in over 130 industries, this circumstance renders lead one of the most important metals from an industrial point of view, just as regarded medically, it is one of the most interesting. In Great Britain and in Western Europe lead is present in ore as galena or sulphide, and as this is rather insoluble in weak acid solutions, miners who blast the ore and are exposed to dust do not suffer from plumbism but from a dust disease of the lung called silicosis. In the Broken Hill mines of Australia lead was present a generation ago in the form of cerussite or carbonate, this, when inhaled as fine dust, is readily soluble, and becomes, not only a source of plumbism, but of the severer type of the malady known as saturnine encephalopathy. It was a fortunate circumstance for the owners of the Broken Hill mines that after the cerussite layer had been worked out the subjacent ore was found to be galena, for the mining of this was followed by a marked declension in the number of cases of lead poisoning. A strange circumstance, however, has arisen at Broken Hill recently there has been a recrudescence of lead poisoning, this was found to be due to the lead ore in places having become changed into cerussite.

It is hardly likely, owing to fuller knowledge among the workers of the value of personal hygiene and cleanliness, improved ventilation where dusty processes are carried on, periodical medical examination of the workers, and enforced compliance with regulations, that the extremely serious and fatal types of lead poisoning with which some of us were familiar thirty to forty years ago, will ever again be met with to the same extent as formerly. In Newcastle upon Tyne, where it was once so frequent, lead poisoning has ceased to be the menace to the health of the workers it was a few years ago, and what is true of Newcastle is equally true of the country generally. In 1900 the number of cases of industrial plumbism reported to the Home Office was 1,058 in 1923 the number was 337. The records for 1924 show a slight increase and particularly is this the case for the manufacture of pottery, but as many of the men and women who have recently died had worked in the pottery trade for from thirty to forty seven years it is more than probable that the seeds of their illness were sown before the introduction of the new methods in vogue. The fact remains that here is no comparison, so far as number of cases and severity of the illness are concerned, between industrial lead poisoning to day and half a century ago.

Nova et Vetera.

MEDICINE IN SIR WILLIAM TEMPLE'S ESSAYS

AMONG his successes in the diplomatic service at Brussels and the Hague, Sir William Temple, weary of the tortuous cross-currents of politics and being also of the type of mind which does not cue to fish in troubled waters, retired to his country seat and solaced himself with his garden and the writing of essays. He was a close observer of affairs, and certain of his essays have interesting comments on medical practice and theory of the time, and notably his essay on the *Cure of the Gout* and that on *Health and Long Life*. In the former he states that no disease had within the compass of his memory so increased in prevalence as the gout, the incidence of which he attributed to an inherited trait, to the constant "use of great tables," to excess of several kinds, and to a sedentary and inactive life. That gout was a frequent malady at the time we know from other sources. Sydenham, a contemporary of Temple, was himself a sufferer; he prescribed as a preventive the libation of Canary wine, thereby showing himself less wise than Temple, who emphasized the necessity of temperance. "Immediately after dinner," says Sydenham, "I am accustomed every day to drink somewhat more than a quarter of a pint of Canary Wine to promote the concoction of food in the stomach and to keep away the gout."

Despite Temple's careful regimen he became subject to gout in middle life, apparently by inheritance, and he heroically adopted the treatment of burning the moxa. This form of treatment, which was introduced from the East Indies, consisted in the application to the affected joint of a pyramid of a special moss, which was ignited at the summit and then slowly burnt down to the skin, the burning was to be repeated a second, a third, and a fourth time until the patient could put his foot firmly to the ground—a form of treatment not to be undertaken lightly.

Temple was in advance of his age in recognizing the important bearing upon health of a life regulated by simplicity. He emphasized the necessity of temperance in food and drink, the importance of exercise, and the value of fruit—"The common ingredients of health and long life are great temperance, open air, easy labour, little care, simplicity of diet, rather fruit and plants than flesh." The period of the Merry Monarch was not one in which it was fashionable to put the reins upon indulgence, and one can hardly imagine Temple as an habitué of the court of Charles II, he was more in his element amongst his books and engaged in the culture of grapes and peonies. He insisted that the true use of wine is as a cordial, that at least it should be reserved for times and occasions of feasting and joy, and on such occasions he would not be unstrained. "The first glass," he says, "may pass for health, the second for good humour, the third for our friends but the fourth is for our enemies."

Criticism is not unknown to-day, and is perhaps not altogether unfounded, of alternating stress on particular diseased conditions and of some efficacy of fashion in remedies. Temple makes similar comment, and tells us that in the course of his experience he had known the changes rung upon richlets, consumption, the spleen, scurvy, ferment of the blood, vapours, and similarly there had been a continued change in the vinting of sovereign remedies. These apparent vagaries of medical fashion have not infrequently been a theme of wit, but Temple shows charity and restraint in his observation.

"Whatever can be said of the uncertainty of their art or disagreement of its professors, they may, I believe confidently undertake that when divines arrive at certainty in their schemes or divinity or lawyers in those of law or politicians in those of civil government the physicians will do it likewise in the methods and practice of physic."

Amidst these uncertainties of the science and art of medicine Temple turned to the practice of temperance and to simple remedies, most of which have passed from use, but some of which remain. Sage he vaunted for consumptive coughs, rue as a digestive and restorer of appetite, saffron

as a cordial (also he praised it but found too offensive for the company he conversed with). Quinine he mentions as of recently established virtue. One remedy he praises highly which seems to have passed entirely from ken, though apparently it was in former days in regular use. Temple adduces the theory that the increased prevalence of stone was to be traced to the introduction of hops, which, he says, took the place of alehoof or ground ivy in the preparation of ale. The use of hops, we are told, was for the better preservation of beer over long sea voyages, but it allowed "the staining of beer to be brought into custom." This substitution was much lamented by Temple, who found in alehoof a sovereign specific, and deemed it "the greatest charm of any plant known amongst us." Hops were introduced into this country in 1525, but their vogue did not become general until the seventeenth century. Previously a variety of plants was used for the seasoning of ale, of which one was the ground ivy or *Ulex glaberrimus*, one of the smaller Leguminæ, its congeners were freely used as herbs.

There is another point of contact between Sir William Temple's day and ours, in that the nation then, as now, had recently experienced the distracting phase of war and unsettlement of received opinion, and it is interesting to note that the essential function of the physician in restoring mental equilibrium as a prime necessity for physical cure was clearly recognized. The methods may not have been the same as those of to-day, but the principle is there, and is well expressed in the following sentence:

"I remember an ingenious physician who told me in the faintest times he found most of his patients so disturbed by troubles of conscience that he was forced to play the divine with them before he could begin the physician whose greatest skill perhaps also lies in the infusing of hopes and inducing some composure and tranquillity of mind before they enter upon the other operations of their art."

Perhaps physicians to-day do not so readily play the divine, but all of experience recognize how large a part the infusion of tranquillity and hope plays in their work.

Thus these essays open a small window through which we gain some glimpse of the world of medicine 250 years ago, and tell us of the impression made on a cultured and observant mind. It has been suggested, whether truly or not, that Halifax had Temple in mind when he penned his aphorism, "He that leaves nothing to chance will do few things ill, but will do very few well." The opinion may be unwarred that were Temple reincarnated as a physician his work in this respect at any rate, would merit the mayor's commendation. J. P.

INTERNAL MIGRATION AND HEALTH

THE Medical Research Council has just issued, as No. 95 of its Special Report Series, a monograph by Mr. A. B. Hill, entitled *Internal Migration and its Effects upon the Death Rates with Special Reference to the County of Essex*, which has both a personal and general claim upon our attention. Mr. A. B. Hill is of the third generation of a family which has achieved high distinction in literature and science, the historical side of the important problem he has selected would have appealed to the scholarly tastes of his grandfather, Dr. Birkbeck Hill, as its physiological aspects must interest the author's father, Dr. Leonard Hill. Anyone would be predisposed in favour of a writer with these hereditary claims on our interest. Mr. Hill is, however, quite able to interest the reader on his own account. It is indeed strange that the subject has had to wait so long for a monographist. Very able men—Dr. Edward Smith in the past, Sir William Hamer in the present generation—have written on some aspects of the hygienic interplay between town and country. Dozens of non-medical writers, usually economists, sometimes propagandists, have described particular facts, but no detailed inquiry under taken primarily from the hygienic point of view and utilizing the whole of the vital statistical data has appeared before.

Mr. Hill stated, as have others, with the datum that in early adult life the rates of mortality in country districts are sometimes absolutely and always relatively unfavourable

Thus in 1901-10, although the standardized mortality (all ages) of males in urban counties was 134 per cent of that of males in rural counties, in the age group 20 to 25 it was only 95.4 per cent of the corresponding rate in rural counties. Similarly the all ages rate upon women was 132.1 per cent of that in rural counties, at ages 20 to 25 only 91.2 per cent. When the comparison is made, not between urban counties and rural counties, but between all urban districts and all rural districts, the absolute inferiority of the rates upon women at young adult ages persists, while for men, although in each age group they die in rural districts at a lower rate than in urban districts (excepting the ages over 85 in one or two years), the rates approximate most closely in young adult life.

This feature is not peculiar to English experience, we find it again in comparing a country mainly non-urban, such as Sweden, with a country mainly urban, such as England and Wales. At all ages between 10 and 25 English rates of mortality are lower than Swedish rates, between 25 and 35 they are not very different, and at all later ages the rates of mortality in Sweden are much lower than in England and Wales.

When comparison is restricted to rates of mortality from pulmonary tuberculosis, the contrast is emphasized. In 1901-10 the standardized mortality (all ages) of males in urban counties was 127.1 per cent of that of males in rural counties, but in the age group 20 to 25 only 79.8 per cent. Females in rural counties had a higher death rate from pulmonary tuberculosis than females in urban counties in each age group from 10 to 35. There is a similar contrast between Swedish and English rates of mortality from pulmonary tuberculosis. An explanation at once suggests itself—the migration from country to town of the healthier and more ambitious adolescents, in search of better paid and more interesting employment, and it is to be remembered that Sweden is a country which in the past has lost many migrants—between 1861 and 1910 the outward balance was almost a million (in a population which increased in that period from nearly 4 million to 5½ million).

But there are difficulties in the way of this explanation. The factors of migration are numerous and complex, to quote Dr. Sjöstrand, of the Swedish Legation:

Emigration often took away the most vigorous and healthy people and thus tended to increase death rates amongst those remaining. But as the admirable research work conducted by the late Professor Sundbarg has proved, emigration was dependent upon a whole series of causes. More often than not people were induced to leave the country by their relatives and friends overseas. Others were driven abroad by a spirit of adventure, by social discontent etc. and in such cases physical health was perhaps a minor consideration. The most important emigration from Sweden took place in the eighties and hardly any unfavourable influence could be traced on the death rates at earlier ages. There was a constant improvement in those death rates with a slight exception for the ages 15 to 25 during the nineties and first quinquennial period of the present century when emigration was already receding.

Mutatis mutandis, these remarks apply to the etiology of internal migration, and some writers have boldly asserted that, so far as tuberculosis is concerned, movement from country to town or transformation of an agricultural into an industrial State is intrinsically favourable to the reduction of mortality, increased opportunities for infection and restriction of fresh air and exercise being more than counterbalanced by the higher nutritional level which, in the past, has usually characterized the increasing village prosperity of an industrial State. It is at least certain that the industrially backward States are those with the highest mortality from tuberculosis, although for technical reasons, displayed in a recent report to the Health Section of the League of Nations by Rosenfeld, comparisons should be made with great caution. It is seen, therefore, that the interpretation of the facts is not simple, so that it is very desirable to be quite sure what are facts before we set to work to explain them.

The first part of Mr. Hill's memoir is devoted to ascertaining what the facts are with respect to movement of population from the rural parts of the county of Essex, taken as a particular example, and the author has analysed the statistical data of a century. He first shows that prior to 1840 there was no systematic movement, but from 1840 to the beginning of the twentieth century there was a large

and steady flow from country to town which was checked between 1901 and 1911. The result was to produce a dearth of young men between the ages of 17 and 35 and of young women between 12 and 30, with corresponding excesses in the centres of immigration, such as London. The favourite age of migration has changed little since 1850, and there is evidence that the migration in the earlier age groups, 15 to 20 for boys and 10 to 15 for girls, is towards local rather than distant towns. In the Essex rural districts the death rates, in comparison with those of England and Wales, are abnormally high between 20 and 35 for males and between 15 and 25 for females. During these fifty years the rates have declined and

there is certainly a suggestion that at these age groups some influence apart from the general improved medical knowledge and application in the fifty years' period, is tending to depress the rural rates and to raise those of London. In other words there is some ground for belief that the lessened volume of migration has reduced the level of the mortality rates at these age groups in the rural areas and has increased similarly the rates for London.

The author then carried out a detailed study of particular districts, and concluded that the migration of adolescents has a definite bearing upon the abnormal height of death rates from all causes in the corresponding age groups, or, in other words, that a positive correlation between volume of migration and height of death rates does exist.

Thus far we have nothing novel in conception, but—an extremely valuable thing in itself—a quantitative measure of the actual effects which in a general way we had supposed would be found, reached by careful and perfectly intelligible statistical analysis.

In the second part of the memoir Mr. Hill breaks fresh ground. He has collected statistics of the after-life of members of families some of whom migrated to towns and others remained in the country. He obtained adequate particulars of 769 persons from 55 different villages. Of the males (402) 182 were migrants, 220 homekeepers, of the females (367) 204 were migrants, 163 homekeepers. They provided in all 14,271 years of life, and have been tested by the appropriate actuarial method. The result is this:

The figures are not very large (though the years of exposure it will be seen, are not inconsiderable) but the results for both males and females are very similar. Whereas the expected deaths of male homekeepers and migrants are 20 and 14 respectively, the observed deaths are 16 and 4, whereas the expected deaths of female homekeepers and migrants are 15 and 11 respectively, the observed deaths are 15 and 2. There is a distinct deficiency of deaths of migrants in each case, a deficiency that appears too great to have arisen solely by chance.

We have not space to recapitulate the author's discussion of the objections which can be urged against the data, but we think they are not sufficient to deprive the result of a certain value and that the direct test is some confirmation of the general statistics. Of course we cannot in this way determine whether the migrants were intrinsically better "lives" or whether their more favourable experience was due to a better environment—that is, not within the scope of such an investigation. But Mr. Hill has been able to throw light upon part of the problem by a study of some factors of country environment, for he has both collected a series of family food budgets and investigated the heights and weights of children in the elementary schools. His budget investigation covered 60 fully recorded diets and a further 38 where the home produce had to be estimated. The average "man" value in calories was 2,900, well below the conventional 3,300, and 45 of the 98 were below 2,750. The diet is, naturally, most deficient for families of three or four children below earning age. Mr. Hill suggests that this might account for the relatively unfavourable death rates of young women, since it would be upon the young married woman that the deficit would tell. This surmise is not, he notes, borne out by the statistics, which indicate that married women in the rural districts between the ages of 25 and 50, when compared with the same class in towns, are at a less disadvantage, in respect of mortality rates, than are unmarried country women in comparison with unmarried townsfolk. A scrutiny of the heights and weights of the school children disclosed no evidence of malnutrition.

A comparison of the heights and weights of the Essex children with similar measurements of a sample of 9,975 American children

gave an interesting result. The latter were classified upon medical examination as excellent or good, 'fair or poor' in nutrition as judged from clinical evidence. The mean measurements were calculated for each group thus classified according to nutritional status in yearly age groups. The heights and weights of the Essex children (differentiating boys and girls) lie between the means of the two American groups. They are somewhat below the good or excellent group, but they are superior to the 'fair or poor'."

On the whole, with a reservation regarding the absolute energy level of the diet, the villages do not come badly out of the test. The housing conditions are, however, extremely bad, and Mr. Hill rightly quotes the rather depressing report made by Dr. Thresh, formerly county medical officer of health, in 1919. In 1921 it was estimated that (in 32 out of the 47 sanitary districts) there were 694 houses definitely unfit and 5,876 houses not reasonably fit for human habitation. One cannot but suspect that in housing we have one of the unfavourable influences contributing to the rate of mortality.

We have already used so much space in indicating the nature of Mr. Hill's inquiry that we must refrain from all but a word of final comment. From a study, however detailed, of a single area we cannot draw any inferences applicable to the whole agricultural population save one that we have had displayed a matter of great importance which can only be fully elucidated by the co-operation of many investigators. It is a subject many aspects of which medical practitioners in our agricultural districts are well placed to investigate, and they will find Mr. Hill's report both stimulating and suggestive.

SECOND CONFERENCE ON STANDARDIZATION OF BIOLOGICAL PRODUCTS

[BY OUR CORRESPONDENT IN GENEVA]

The second international conference on the standardization of biological products was held at Geneva from August 31st to September 3rd under the presidency of Dr. H. H. Dale, F.R.S. of London and was attended by seventeen representatives from various countries. The members of the conference were welcomed by Dr. Ryghman on behalf of the Health Section of the League of Nations. The main business of the conference was to discuss the standardization of such products as pituitary extract, insulin, digitals, salivarin, thyroid gland, ergot, and others, and each of these was the subject of a good discussion, and resolutions were formulated which received the unanimous support of the conference. Indeed, the unanimity was such that when at the conclusion of their labours, the members of the conference were invited to see the Council of the League of Nations in session, Dr. Dale suggested that it might be better if the Council of the League attended a session of the conference to learn how to do things unanimately!

One resolution of a general character, relating to the international control of the traffic in secret and proprietary remedies put forward at the suggestion of Dr. Ryghman, was also unanimously carried. It ran as follows:

That the members of this Conference representing expert pharmacological opinion from many countries recognize and welcome the effort made in different countries to control the traffic in secret remedies and in a certain kind of proprietary remedies the existence of which they regard as detrimental and as a menace to public health. They express the hope that the Health Committee of the League of Nations will be able to find means to coordinate and centralize such efforts so as to render them international in their effect and provide a basis on which the different countries may be able to deal with this matter, in the interest of the health of their own people.

The first product which received detailed consideration by the conference was pituitary extract upon which a report was presented by Professor Voegtlin. After a somewhat lengthy discussion resolutions were arrived at, declaring that the dry (acetone) extracted substance of the fresh posterior lobe of the pituitary gland, which was recommended by Professor Voegtlin to the Edinburgh conference as suitable for adoption as a standard of activity for pituitary extracts and which has since been

adopted as a standard for this purpose in the United States Pharmacopoeia (tenth edition), should be now definitely accepted as the international standard, that the authority responsible in any country for biological standardization should prepare such quantities of the standard as were needed for distribution, and that the health organization of the League should be asked to furnish a small sample of the standard as originally prepared for examination by the Edinburgh conference to any authority which might require it for the confirmation of its own national standard. Various other recommendations were made with regard to the biological assay of this product, and it was also decided that it was desirable to express all pituitary extracts in units of activity, for this purpose the activity corresponding to 0.5 mg. of the standard powder is to be defined as one unit. Thus the official liquid extract of the United States Pharmacopoeia (tenth edition) would contain ten international units of activity per cubic centimetre, while that of another country might be made to contain a larger or smaller number of such units in accordance with the prevailing clinical practice in the country concerned.

Professor Macleod introduced the subject of insulin and recommended the adoption as the international standard of the dried preparation of insulin hydrochloride which, at the request of the Edinburgh conference of 1923, has been made at the National Institute for Medical Research, London, 1 mg. of this preparation to be regarded as containing 8 units of insulin. Professor Meyer mentioned a new method devised by Professor Loewy of the University of Graz, depending upon, what Professor Loewy held to be proved, in alteration by insulin of the distribution of dextrose between the plasma and corpuscles of shed blood. It was agreed that this method deserved further careful investigation but that no recommendation could yet be made as to its adoption. The recommendation made by Professor Macleod was agreed to, and it was arranged that the standard preparation should be kept by the Medical Research Council, which would undertake to test the permanence of its potency from time to time, and that samples of the preparation should be sent to some responsible organization in each country which would undertake its further distribution to testing laboratories.

With regard to digitals the conference agreed that an international standard dry powdered preparation of the leaves of *Digitalis purpurea* should be made of the same strength (10 per cent) as the experimental standard powder prepared in accordance with the decision of the first international conference at Edinburgh. The standard should be prepared by the mixture of ten different powders made from leaves properly dried at 55° to 60° C., should be adjusted by biological assay on cats, and distributed for international use, the permanence of its activity to be annually controlled.

The conference accepted the principle of the standardization of salivarin and its derivatives in relation to permanent standard preparations, and Professor Kolbe of Frankfurt was asked to accept the responsibility of preparing, maintaining, and distributing the standards for the various products of this class. It was agreed, further, that every batch of the remedies in question, before issue for therapeutic use, should be tested on normal animals for toxicity, and on animals infected with a suitable strain of pathogenic organisms for therapeutic potency.

Thyroid gland preparations were also discussed, and it was agreed, on the suggestion of Professor Reid Hunt, to adopt the standard of iodine content. The question of ergot was introduced by Professor Tiendelenburg, who said that, of a number of testing methods he had examined, a test based on the paralytic effect of these alkaloids on the inhibitory action of adrenaline on the movements of the isolated intestine of rabbits and guinea-pigs appeared to be most promising. The conference decided that the question of the biological standardization of ergot was not yet ripe for final decision.

After various other substances had been considered, Professor Pontsson presented a memorandum dealing with methods proposed for standardizing for vitamin content the substances used in medicine for supplying vitamins to patients. He recommended the method already adopted in the United States Pharmacopoeia (tenth edition) for standardizing cod-liver oil for the growth promoting factor

(vitamin A) He stated that tests were already available, though less certainly quantitative in their indications, for the antirachitic vitamin, the water-soluble growth-promoting vitamin, and the antiscorbutic vitamin A. Discussion ensued, in the course of which it was suggested by Dr Dale that the present conference was hardly suitable for the discussion of the whole question of the biological standard of vitamins. It appeared to him that such a discussion could more suitably be undertaken by a special conference analogous to the serological conference, attended by recognized experts in this special branch of inquiry. With regard to the proposed biological assay of cod-liver oil for vitamin A, he thought that the present conference might usefully promote investigation, in connexion with the reaction recently described by Drs Rosenheim and Drummond of London, which was believed by those workers to be specific for vitamin A and to be suitable for application as a quantitative colorimetric test. He suggested that Professor Poulsen might possibly be able to obtain a series of samples of cod-liver oil exhibiting widely different degrees of growth promoting activity, and undertook to endeavour to arrange for a comparative investigation of these by chemical and biological tests in London, and, with Dr Voeghtlin's co-operation, possibly in the United States as well. The conference passed a resolution affirming that the preparations used in therapeutics to supply vitamins to patients should be standardized as accurately as possible, such for its content of characteristic vitamin or vitamins, that the preparation for which such standardization appeared at present to be most important and most practicable was cod liver oil, vitamin A being the constituent of this oil which could be most accurately assayed, and that action be taken along the lines suggested by Dr Dale in his remarks just quoted.

The conference decided to take no action at present with regard to cannabis indica, squill, and certain other preparations.

THE PUBLIC HEALTH ACT, 1925

UNDER date September 4th the Ministry of Health has issued to public health authorities the following circular letter relating to the Public Health Act, 1925.

This Act covers a wide range and much enlarges the powers of local authorities. It is important that it should be familiar to councils and their officials and it is requested that it may be specially brought to the notice of the principal officers whose duties will be affected. It has been thought that it will be helpful to local authorities to deal fully in the summary with the provisions of the Act and it is hoped that it will provide information on a number of matters on which advice may be desired. The Act comes into operation on September 8th. Many of the powers will be in force only if the appropriate provisions are adopted after that date by the local council except those which may be exercised by county councils. In the case of urban districts with a population of less than 20,000 persons the consent of the Minister is necessary to the adoption of some special provisions. In the case of rural districts a number of provisions which are primarily suited for urban areas cannot be adopted by the council but can be put in force by an order of the Minister. The position in these matters is explained fully in the summary. The attention of urban authorities is called to the duty which is placed upon them by Section 84 of the Act to prepare, within six months after the 8th instant, a list of the districts within their area which are repayable by the inhabitants at large. The additional powers placed at the disposal of local authorities by the Act should be of material assistance to them in dealing with local problems and the amendments which have been effected in the law will be a useful preliminary step towards the consolidation of the Public Health Acts.

The summary referred to in the circular extends to forty pages, and will be of great value to the authorities and their officers charged with the administration of the Act. It is impossible within any reasonable limits of space to summarize what is itself only a summary, but a brief indication may be given of a number of the matters dealt with. The Act is in nine parts and contains eighty-seven sections. It relates only to England and Wales, and a good deal of it is adoptive under central sanction. The nine parts are (I) Preliminary, (II) Streets and Buildings, (III) Sanitary Provisions, (IV) Verminous Premises, etc., (V) Watercourses, Streams, etc., (VI) Recreation Grounds,

(VII) Infectious Disease and Hospitals, (VIII) Miscellaneous, (IX) Baths and Washhouses.

Part I deals with adoption, application, appeals, etc. Part II (Streets and Buildings) is adoptive except in so far as it confers powers on county councils. It covers many administrative details—drinking fountains, fire alarms, naming of streets, paving and draining, lopping of overhanging trees, wireless installations, construction of bridges, width and widening of streets, etc. Part III (Sanitary Provisions) is adoptive. It treats of drains and sewers, prevention of entry of petrol into sewers, ventilation of soil pipes, tents and vans, and questions as to the establishment of offensive trades. Part IV is adoptive, and is devoted to verminous conditions of articles, houses, and persons, power of entry, and cleansing stations. Cleansing may be compulsorily done under certification by the medical officer or sanitary inspector, and subject to reservations in the case of verminous persons. The cost is to be borne by the local authority. Part V (Watercourses, Streams, etc.) is adoptive and provides for the covering of watercourses and ditches, repair and cleansing of culverts, and local authority's defrayment of costs of execution of works. Part VI (Recreation Grounds) is not adoptive. It gives further powers as to parks and pleasure grounds, including restrictions as to concerts, entertainments, and cinematographs, provided by a local authority, and limitation of a local authority's expenditure on bands, concerts, etc., to a rate of 1d to 2d in the £. Parts of parks or pleasure grounds may be set apart for accommodation for cricket, football, etc. Part VII (Infectious Disease and Hospitals) is not adoptive. Certain of its provisions apply to county councils only, others to county and district councils. In connexion with infectious disease at common lodging houses, it provides for right of entry for medical examination, and also for closure. It defines dangerous infectious disease in relation to notification. It makes clear that the Minister of Health may invest a county council with the power of providing a hospital for the reception of patients, and may make regulations as to parish assessments for cost of maintenance of patients.

Concerning the important and difficult question of compulsory isolation of tuberculosis, it is enacted that county and other councils may apply to a court of summary jurisdiction for an order for removal to hospital or institution of an infectious case of pulmonary tuberculosis, and detention there for a period not exceeding three months. The powers of removal may be exercised contrary to the wishes of the patient, but certain safeguards are provided. (1) The section is restricted to patients whose lodging or accommodation prevents the adoption of proper precautions against spread of infection, or who are not taking such precautions, and in either case it must be shown that serious risk of infection is caused, (2) a suitable hospital must be available, (3) the cost is to be borne by the county council or local authority, and these bodies may be required to contribute towards the maintenance of dependants, (4) the first period of detention can only be extended if the court is satisfied that the risks to others would again exist and (5) application may be made by or on behalf of the patient for rescission of the order after six weeks from its date.

The extended use of ambulances, etc., is provided for. It is made clear that reasonable subscriptions or donations to voluntary hospitals or institutions may be made by local authorities, but the expenditure is not to exceed a rate of 1d in the £ of assessable property. Local authorities are empowered to provide conveniently situated houses for hospital officers and servants.

Part VIII, entitled Miscellaneous, is not adoptive. The Blind Persons Act (1920) deals with the welfare of the blind, but the new Act sanctions arrangements relating to prevention of blindness and the treatment of disease or injury of the eyes. Residence in a hospital or institution for the blind is not to affect the responsibility of the area in which the patient previously resided, for his maintenance. Other provisions of Part VIII include powers of local authorities to provide health lectures, pictures and other health information, subject to restrictions and conditions. Parking places for vehicles may be provided, also grounds for cricket, football etc. either by individual authorities or jointly. Where a local authority has provided a public slaughterhouse or market, it may also provide a cold storage or refrigerator, with consent of the Minister, and may fix reasonable charges for its use. Sanitary precautions are to be observed whenever food is prepared or kept for sale. The precautions specified resemble those relating to balhouses. Rag and bone dealers must not sell food or toys. Penalties may be imposed for neglect of traffic directions and for dangerous driving. Persons waiting to enter public vehicles may be arranged in queue and even in rural districts vehicular traffic at railway stations may be controlled. Part IX (Baths and Washhouses) is the only part of the Act which extends to the administrative County of London. Charges

for the use of these conveniences are dealt with, also the closing of swimming baths in winter, or their uses for other purposes.

It will be seen from the above notes, which are far from complete, that the new Act deals with many details which the working of existing Acts has shown to be necessary. It is a Public Health Act, not a Local Government Act, and is not intended to remove existing anomalies regarding the areas and population of so-called urban and rural districts as at present constituted.

Scotland.

SCOTTISH SANITARY CONGRESS

THE fifty-first annual congress of the Royal Sanitary Association of Scotland was held at Hivial on September 3rd and 4th. Mr John Halliday, sanitary inspector, Port Glasgow, read a paper entitled "The inspection of our daily bread and its allies." He said that though certain provisions relating to some articles of food had been added to the provisions of the Sale of Food and Drugs Act, 1875, the foundation of all these was contained in the original Act. In the fifty years that had passed there had been a tremendous development in the preparation, transport, storage, and distribution of foods, all creating fresh problems, and it did not appear that the basis of the Act was broad enough to deal adequately with existing conditions. There was no amendment of the Act designed to incorporate the great increase of scientific knowledge regarding the dangers of dirt and decomposition. The lecturer said that his experience as an inspector for a quarter of a century had taught him that nine-tenths of the pollution of food was preventable. Vermin should be kept out of stores, dirty places should not be permissible as food stores or food factories, and dirty persons should not be allowed to handle food in preparation. The road to health was beset with pitfalls dug by the lazy, the incompetent, the crafty, or the unscrupulous dealer, whose chief aim was self-interest. A short paper was also read by Dr Gerald Leighton of the Scottish Board of Health, in which he expressed the opinion that a Pure Food Act was the most urgently required of any health enactments. Legal standards with regard to what the important foods should contain were very much needed. He hoped that the general body of consumers would before long demand that we should follow other countries in regulating these matters by a comprehensive Pure Food Act. Dr A S M Macgregor, interim medical officer of health, Glasgow, contributed a paper on modern methods in the prevention and treatment of infectious disease. Referring to tuberculosis, he said that recently Professor Calmette and his colleagues had produced a strain of attenuated tubercle bacillus capable of producing antibodies in laboratory animals. It was expected that by inoculating calves with this soon after birth they could be made to resist subsequent infection with tuberculosis. This would have a very important effect in the production of tubercle-free herds of dairy cows. Preliminary results in the preventive treatment of young children by this means had just been reported to the Academy of Medicine in Paris.

MODERN TREATMENT OF INSANITY

The annual report of the Royal Asylum at Montrose for the year ended May 15th, 1925, contains some interesting observations by the physician superintendent, Dr C J Shaw, upon modern developments in the treatment of the insane. The number of certified patients remaining on the register on May 14th, 1925, was 726, including 349 men and 377 women. Including 28 voluntary patients, the total number in residence was 754. During the year 841 cases had been under treatment, with a daily average in residence of 752. The death rate on this number had been 8.07 per cent (27 males and 31 females). The average age at death had been 60.7 years, including 22 persons over 70 years of age, of whom 3 had exceeded the age of 90. The average age on admission had been 45.9 years, though 13 patients had been admitted when over the age of 70 years. Attention is drawn to the fact that the percentage of senile

cases is not quite so high as in previous years, and that if nursing facilities could be provided in parish homes or elsewhere certification would not be necessary for many of these aged persons. Recovery could not be expected and mental symptoms were due simply to the general systemic breakdown, so that many died soon after removal to the asylum. With regard to the causes of mental attack, the exciting and predisposing causes tabulated for the 131 admissions show that moral influences including domestic trouble, pecuniary worries, fright, and war stress had acted as an exciting cause in 35 cases (26 per cent), and physical causes, such as old age, epilepsy, and bodily diseases, in 81 cases (61 per cent). Heredity had been ascertained as a predisposing factor in 44 cases, or one third of all the admissions. Of the cases admitted during the year, 31, including 12 males and 19 females had at some previous time been already certified. Alcoholic indulgence was assigned as a cause only in 7 cases, but the critical periods of life had been found to bear a distinct relationship to the onset of mental trouble (puberty 3 cases, adolescence 10 cases, characteric 8 cases and old age 13 cases). Fourteen of the cases had already been mental defectives. With regard to discharges, 57 in number, 29 had recovered, 16 had improved sufficiently to return to the care of their friends or to be boarded out, while 12 were transferred as not improved. Attention is drawn to the fact that in cases with an acute onset the symptoms are usually so marked that admission has to be sought at an early stage, and the prognosis is therefore more hopeful. Unfortunately, however, in many cases the onset is insidious, and medical advice is not sought or not followed until too late. There would be less hesitation in attending at a general hospital where a mental specialist might be seen, treatment suggested, and touch maintained with the patient. The report points out that in many instances the effect of this would be to arrest the progress of the mental disease and that if certification should become necessary it could be carried out at a stage when the prospects of recovery were more hopeful. Twenty, or 34.4 per cent of the private cases had been admitted as voluntary patients, and there had been an increasing tendency to this method of admission in recent years. The chief obstacle to early treatment of mental disease were pauperization, certification, and the stigma which attached to asylum care. The first two of these would be largely removed if the voluntary system of admission were made available for pauper patients and the attitude of the public would be changed towards the last if asylums came to be regarded more in the light of mental hospitals than as houses of correction or detention. In regard to this particular asylum it is urged that a step in this direction has been taken by staffing three wards in the hospital block and three wards for chronic and convalescent male patients with female nurses.

PROVISION FOR MENTAL DEFECTIVES

The Edinburgh District Board of Control has recently purchased the estate of Kellistoun in the parish of Ratho for the purpose of providing accommodation for the housing of mental defectives. This board already possesses Gogar burn, a house and estate in the immediate neighbourhood, in which mental defectives have been segregated for some years past. It is expected that provision will be made in the course of a comparatively few years for the settlement, in the house and in cottages still to be built, of approximately a thousand mental defectives. Under the scheme of the Board of Control for Scotland, by which the larger towns are to provide accommodation for the mental defectives of the surrounding sections of the country, those mental defectives, for which Edinburgh is responsible, will be drawn from the whole of the south-east of Scotland. Kellistoun extends to over 360 acres, and seems to be admirably adapted for the purpose in view.

ROYAL INFIRMARY, EDINBURGH. RETIREMENT OF LADY SUPERINTENDENT

A committee of the visiting staff of the Royal Infirmary, Edinburgh, waited upon Miss A W Gill, lady superintendent of nurses on August 25th, for the purpose of presenting her with two pieces of plate on the occasion of

her retirement from her present post Miss Gill retires at the end of this month and is succeeded by Miss Bladen, who at present holds the post of assistant superintendent. The presentation took the form of a large inscribed silver tray and bowl, which are replicas of two of the larger pieces of the ancient Roman Treasurers' treasure. Dr Haig Ferguson, chairman of the visiting staff, referred to the great regret felt by his colleagues at Miss Gill's approaching departure.

England and Wales.

SANITARY CONFERENCE IN LIVERPOOL

THE thirty eighth annual conference of the Sanitary Inspectors' Association was held in Liverpool under the presidency of Sir William J. Collins, K.C.V.O., M.D., on September 9th, 10th, and 11th. Some 750 delegates and representatives of local authorities were present. Founded in 1885 by the father of British sanitary science, Sir Edwin Chadwick, the association has steadily grown, and its work may be justly regarded as ancillary to preventive medicine. The presidential address passed in rapid review the progress of knowledge during the last one hundred years. The speaker referred to the centenary of Huxley's birth and his life work, which he brought before his hearers in juxtaposition with the recent State trial of a school-teacher in Tennessee. Religion and science alike, he said, were in quest of truth, stood in no need of the protection of authority, but flourished best in an atmosphere of free and unfettered thought. Passing to the subject of evolution and disease, Sir William Collins urged that if it be true that in the life-history of the lowest organic things by the momentous influences which determined plagues and pestilences, it was reasonable to believe that in organisms whose cycle might be less than an hour and whose rate of propagation was incalculable, evolution might be powerfully at work, eventuating in the survival of those most fitted to their environment. Man's influence in this, as in other directions, might modify natural selection, and by acting in accordance with law learn to conquer Nature by submitting to her. The president then alluded to the cancer germ, and the various statements made recently by observers, showing that the whole subject still required most painstaking research before any definite conclusion could be reached. Neither the parasitic nor the chemical theory settled the question, and Sir William thought that by a return to cellular pathology, illuminated by evolutionary principles, they might seek for the intrinsic rather than the extrinsic causation of cancer. His concluding remarks dealt with the imperative need for reform in death certification and coroners' law.

Milk Slums and Rehousing

Clean milk and its distribution was fully discussed. Not palatial cowsheds so much as systematic methods of ideal cleanliness in utensils and the importance of the human factor were the points to be kept constantly in view. In short, the public and all concerned with milk production required to be educated in the importance of physiological cleanliness. Slum clearances and rehousing called forth an animated discussion, especially on the latter topic. The chairman of the Edinburgh Public Health Committee expressed his astonishment that Liverpool and London were going against all the teaching of the last fifty years by proposing to aggregate populations in high tenement dwellings. In Scotland they had been doing their best to get rid of the "vertical slums" which all medical officers and sanitary inspectors had declared to be adverse to the health of the individual. Some of the speakers thought that motives of economy were the deciding factors in erecting barrack tenements, and apparently no speaker spoke with enthusiasm in favour of such dwellings.

Smoke Abatement Marine Sanitation

The domestic chimney was blamed as much as the factory one for air pollution, and the Liverpool city analyst stated that in one year in Liverpool the rainfall in twelve months

brought down as much as 550 tons of dirt and carbonaceous products to the square mile. One delegate suggested that a new type of fuel, combining the advantages of coal and coke and eliminating their drawbacks, was urgently required. This would be less costly than converting millions of fireplaces into gas or electric heaters. A plea was put forward for better hygienic quarters for our seamen, and it was stated that, instead of lagging behind, we, as a maritime nation, should set up a higher standard than the Board of Trade at present required. The Ministry of Health and the port sanitary authority should undertake this duty.

TREATMENT OF SCHOOL CHILDREN

The Board of Education has now confirmed, with one or two minor modifications, the draft regulations for special services published in February, and these regulations including those for the medical inspection and treatment of children in elementary and secondary schools, can now be obtained in a single pamphlet. Each local authority must appoint a school medical officer approved by the Board, and, if required by the Board, submit annually a statement of its proposals for the special services of medical inspection and treatment, the provision of meals, the organization of physical training, and the cure of defectives. Emphasis is laid upon the need for securing a proper relation between these special services and other educational and public health services, with such adaptation to local needs as will ensure the provision of a comprehensive scheme for promoting the physical and mental development of all children in the area of the authority. Each child in a public elementary school must be medically examined on admission, and on reaching the ages of 8 and 12 years. Arrangements must be made for treating children with defects of the eyes and teeth, minor ailments, and enlarged tonsils and adenoids. Students under the age of 18 at secondary and continuation schools, pupil teacher centres, and junior technical schools must also be supervised medically, and treatment may be arranged. In the case of unsexed schools adequate arrangements must be made with regard to health, nourishment, and physical welfare. Records must be kept, and returns furnished as desired. If the local sanitary authority, or any two members of it acting on the advice of the medical officer of health, require either the closure of any premises used for the performance of a special service, or the exclusion from it of certain pupils with a view to preventing the spread of disease, such requirements must be complied with at once. Where meals are supplied to children attending public elementary schools the regulations laid down provide for the keeping of records of the effect of the meals on the physical and mental condition of the children, and the association of the school medical service with the planning and administration of the arrangements.

PUERPERAL FEVER BEDS IN LONDON

The Minister of Health, in a recent circular, states that he has had under consideration the hospital accommodation available in London for cases of puerperal fever, and he is satisfied, as a result of inquiries, that further special facilities, both for nursing and for medical treatment, are required, with a view to reducing the mortality from this disease. Arrangements have accordingly been made by the Metropolitan Asylums Board whereby in future the cases of puerperal fever referred to the Board will be concentrated, as far as practicable, in three of its institutions—namely, the Finsen Hospital, Homerton, the North-Western Hospital, Hampstead, and the South-Western Hospital, Stockwell—where special wards will be set aside for these cases and special medical and nursing staffs provided. The Metropolitan Asylums Board has also, with the Minister's approval, appointed an obstetric consultant at these three institutions. It is recognized that suitable accommodation for cases of puerperal fever is available at other institutions, but the Minister trusts that the metropolitan borough councils will take steps to secure, as far as practicable, that full use is made of the accommodation provided by the Metropolitan Asylums Board.

¹ Board of Education Statutory Rules and Order, 1925 No. 835. Price 4d. net.

Commission announces that the good round figure of 10,000 additional beds is needed in England and Wales. Apparently the 10,000 must spring up, like mushrooms, in a night. There is no time to wait, no time to make small additions in the more urgently pressed districts, no time to make up gradually the loss in the war. The 10,000 in a night are beyond the resources of the voluntary system. Let the taxpayer stand the racket. And it once eminent members of the Association leap in to hit the scheme.

There is no reason to deny the need for more hospital beds, even if the number required may not be quite so round as the Commission suggests. Nor is there reason to deny the services rendered by the State in many medical problems. But at a time when economy is said to be urgently necessary there are a few questions which may be raised about precipitate action towards the socialists' ideal. For example, how does this country stand in matters of health as compared with other countries? Are we falling so much behind other nations in healthiness that nothing but the immediate provision by the State of 10,000 beds will save us? Must the envious eyes of Mr. Souttar be at once gratified by more superb clinics than those of our friends abroad? And must reluctant Divisions be once more stirred up to elect representatives on Local Voluntary Hospital Committees for the purpose of booming Mr. Bishop Humber's hospital policy, or defending the rights of Dr. Flemming's cottage hospitals?

In answer to all these questions there appears in the Commission's report one small gleam of hope—namely, that in the last two years there has been improvement in the expansion of hospitals, an improvement which is noted as evidence of the vitality of the voluntary system. Might not the socialist zeal of our conservative reformers be curbed by fanning this gleam of voluntary effort into a ruddier glow? The gleam suggests that there may be methods by which the 10,000 beds might be got by degrees, without the intervention of State subsidies. The methods may require effort, and it is easier, no doubt, when tired of effort, to nationalize mines, railways, transport, and hospitals. It is doubtfully desirable to do so.

The Commission's report seems to have one merit which has not been noticed. It appears to have cold shouldered the other idealistic scheme—that of the Minister of Health's Consultative Council on Medical and Allied Services—I am, etc.,

FELICAD Sept 13th

CHAS BUTLER

THE SURGEON AND THE PUBLIC

SIR,—In spite of the advance in medicine and the more striking progress in surgery in recent years, I am sure that all physicians and surgeons who have the cruse of medicine at heart must feel much dissatisfaction with the present state of things. For one reason or another patients drift on with their illnesses to a stage at which it is impossible to effect a cure or some drastic operation has to be performed, when a relatively simple procedure at an earlier date would have sufficed.

A critical review of surgical literature and statistics shows that surgeons are operating in a distressingly large proportion of cases for the complications of surgical lesions, and not for the primary surgical complaints. For example, the Registrar-General's statistics show no diminution in the death rate from acute appendicitis, and if we put side by side the statistics from any large general hospital, which will show that in the majority of cases coming to operation the infection has already spread beyond the appendix, it is evident why the results are still so far from satisfactory. The same may be said of many other diseases.

How are we to improve things? By education. In some way it should be made easier for general practitioners to see what is going on at the teaching hospitals, so that they may keep in touch with old and new methods of investigation and treatment, especially as applied to their own cases after admission. It would be of immense value to include as a part of the curriculum at least a six months' appointment at a teaching hospital immediately after the final examination, even if this meant taking six months out of the pre-examination stage, for I believe more useful know-

ledge is acquired after the examinations are out of the way. At present too many men go into general practice without any post-graduate hospital experience. There would be difficulties at some of the larger schools, but if it were a compulsory regulation these difficulties would have to be, and could be, overcome. Increasing the number of appointments and a redistribution of the students would go far to put this right.

I have mentioned medical education first, but I do not wish to imply that the medical profession alone is to blame, much educational reform has been achieved already in this respect. In my experience the harm has been done in many cases before a medical man has been consulted. I will mention only two conditions—acute appendicitis and cancer. In the first, the patient, usually a child, complains of acute abdominal pain, and is promptly given an aperient by its parents, who act according to the popular tradition that "a good clear out" is all that is required, when the expected cure is not produced the doctor is sent for, maybe two or three days after the onset, perforation having in the meantime been precipitated by the aperient. In the second condition there is such a universal dread of cancer, such a feeling of certainty that it is the disease contracted, such a profound conviction that nothing useful can be done, and such a terror of the operation which is felt to be the inevitable outcome of consulting a doctor, that the period in which surgery can be depended upon to effect a complete eradication is already gone before a medical man is consulted. In other words, the patient does not give his doctor a fair chance. Come, it is time is inidious in onset but it gives rise to early signs and symptoms which are sufficient to warn those who do not wish to deceive themselves. The great field for education lies in this direction, and hitherto no attempt has been made to tackle it with energy and determination. We have everything at hand for such a campaign if we decide to act—namely, wireless and the press.

I believe that the broadcasting of indisputable, elementary facts would produce an immediate and extensive permeation which would have immense benefit. A person appointed by a responsible body, such as the Ministry of Health, would be listened to very carefully, for discussions on health are the most enthralling of all topics to a large section of the community. It would be easy to think of scores of simple facts to broadcast, but if only one—namely, that it is dangerous to give aperients for acute abdominal pain without the sanction of a doctor—was thoroughly thrust home, I believe we should see an immediate and vast improvement in the results of operation for acute appendicitis. At any rate it would be an easy way of testing the value of this educative method. Until there is a more intimate knowledge on the part of the public of such simple medical facts, I can see little hope of any rapid advance in the earlier recognition and treatment of disease. It is a tradition of medicine to condemn advertisement by its practitioners, but it seems to me a calamity that elementary knowledge of an official kind should be withheld from the public, while pernicious statements on behalf of quick remedies are allowed to be published wholesale.

In the distant future the need for surgery will no doubt steadily diminish as the efficiency of preventive medicine and education increases, but this is not the trend of affairs at present. The field of surgery is extending and also the number of operations in each area, but opportunities for early surgical intervention lag lamentably behind. However, taking things as they are, much can be done by giving oneself wholeheartedly to the attainment of the utmost possible for each patient as he comes, and here I think there is room for much improvement in surgery. It should be the aim of surgeons to do all in their power to remove from the public mind the widespread terror of operation. Fear of death is at the root of this terror, and much good would accrue here from the occasional surgeons relinquishing their efforts to perform serious operations, this is work for professed surgeons through whose hands such cases are constantly passing, and whose results are, therefore, better. Again, it is a reproach to surgery that a second operation should have to be performed for a condition which ought to have been cleared up on the first occasion. Recurrence of a hernia, overlooking a stone in the common duct when

doing a cholecystectomy, or injuring the duct, doing an operation for a condition diagnosed clinically but not found at operation, and not exploring the whole abdomen, thus missing the real lesion—these are some of the more common reasons for the necessity of secondary operations, which should very rarely arise when the primary operation is done by a competent surgeon. It is not difficult to appreciate the effect of this kind of thing on the attitude of the public towards surgery. Another matter to which the careful surgeon pays great attention is preparing his patient for operation. It is not enough to decide that an operation is necessary and to proceed with it forthwith. The utmost pains must be taken to ensure that the patient is in the best possible condition to undergo it. This may take much time, but the labour will be well repaid, and the public ought to be in a position to know that they are getting all that is necessary in this respect, as well as the requisite skill in the actual operation.

Many other things can be done to help towards creating a better popular feeling towards surgery, but I will only note one, and that is diminishing the dread of the anaesthetic. Since it has become the custom to give a preliminary injection of scopolamine, morphine, and atropine, the mental alertness of the patient prior to the anaesthetic has been much reduced. But to keep him in this muzzy state he must have the least possible stimuli to disturb him. Noise, light, talking, and jolting on an ambulance should be avoided. It is no use stupefying the patient with morphine and then making him walk to the theatre, though this is not infrequently done. When all these precautions have been taken, and the patient is anaesthetized with gas and oxygen in the first place, it is quite a common experience to hear him ask, as he comes round, when the operation is going to take place.

Attention to such matters as I have referred to should do much to encourage an attitude of mind towards surgery which will lead to the getting of cases at the earliest possible moment. But even with perfection in the practitioner, a perfect result cannot be attained without the utmost co-operation on the part of the patient, and this, I hold, can only be achieved by a well organized and sustained campaign of public education—I am, etc.,

Leeds Sept 14

E R FLINT

"GENERAL" OR "SEPTIC" PERITONITIS

SIR,—I have been greatly interested in Mr A J Blackland's article on the treatment of acute spreading peritonitis, as published in your issue of June 6th last (p 1037). He gives an admirable summary of Mr Sampson Handley's methods in the treatment of these desperate cases, mentioning that three out of the four cases reported by Mr Handley recovered.

Mr Blackland concludes an interesting account of his own case with the remark that he presumed it could be "wise to combine cecostomy with the anastomosis" (ileo- or jeuno-cecostomy), as recommended by Mr Sampson Handley. Undoubtedly it would. But it may be well to point out that a number of these desperate cases may be cured by the simple operation of cecostomy alone, as advocated and successfully carried out by the late Arthur Nixson in his work as gynaecologist to the Perth Hospital, Western Australia, and reported under the heading of "Intestinal drainage in septic peritonitis," at various times, in the *Medical Journal of Australia*, the *Lancet*, and the *BRITISH MEDICAL JOURNAL*. A later paper embodying his matured views on this subject appeared in the *British Journal of Surgery* of July, 1917, with the title "Cecostomy in septic peritonitis." The last six cases treated by him at the Perth Hospital all recovered with the simple operation of cecostomy alone and have been fully reported elsewhere—I am, etc.,

TESTS FOR DRUNKENNESS

SIR—In your issue for September 12th (p 495) Mr Howard Stratford advocates the formation of a committee to determine the tests for drunkenness. Might I venture to suggest that the time has arrived to drop the use of

these words "drunk," "drunkenness"? Are they not a complex of two often conflicting ideas which, in interpretation by the police and the doctor, lead to different conclusions, and possibly to the unedifying spectacle of doctors differing in public courts?

During the war an adjutant, keen to remove an undesirable officer from his regiment, caused me to be called to see this officer, and later involved me in a court martial. My senior medical officer (an old I M S colonel) advised me not to use the word "drunk", not to accept it when an endeavour would be made to put it into my mouth, and to content myself with a statement that "in my opinion the officer was, when I saw him, not capable of performing his duties, as he was at that time suffering from an excess, for him, of alcohol." The defending counsel, supplied with medical tomes, was waiting to tie me up in a knot, the presiding general and his colleagues—obsessed and bound by the King's Regulations—tried to force "drunk" upon me, and looked helpless and foolish when I stuck to my statement, asking them what they meant by "drunk." The officer got off!

Many an elderly lady patient takes a nightcap which is, in its desired action, undoubtedly an excess of alcohol for her, but did her doctor tell her that she was drunk she would be very much scandalized. Also, many a highly placed personage, after a banquet, is suffering from an excess, for him, of alcohol, and yet is capable of performing his immediate duty of walking home, although he could not have managed a motor car. In the former position the police would leave him alone, whereas the doctors who might see him would, by calling him "drunk" in both positions, have brought that highly placed personage into a police station and before a magistrate.

If the suggested committee of investigation would condemn as obsolete the use of these words and would elaborate definitions and symptoms by which each individual instance could be judged by all parties concerned, it would help undoubtedly to remove the fog which at present surrounds the question—I am, etc.,

Hove Sept 12th

E ROWLAND GUTHRIE

SIR,—Mr Howard Stratford's letter in the *JOURNAL* of September 12th (p 495) is of interest in more ways than one, as it shows the very vague ideas which the otherwise intelligent man has as to the methods applied in examining a case of "drunk in charge" (of a motor car). We are all agreed that the signs he enumerates "are not necessarily signs of drunkenness in themselves, or even if associated." No sane medical examiner would omit to take into consideration emotional stress or temperament, but even more so would he make careful inquiry into the whole circumstances and hear the story which the detained driver has to tell before forming any conclusion.

The experienced divisional police surgeon realizes more than most men the gravity of such a charge, and is unusually careful in his examination of a person detained on such a charge. He has the great advantage, however, of seeing the case much earlier, as a rule, than any other medical man—although, in our experience, even when a second medical man has been called on the prisoner's behalf it is very rarely found that the second opinion disagrees in any material sense with the first.

Mr Stratford does not realize that quite a large proportion of such cases are "tuned down" on the police surgeon's report and are not charged at all, the public only hear of those who are charged.

The onus of conviction does not rest upon the police surgeon's report, which is merely a medical opinion, given in the interests of the public, it is the magistrate who has to sift all the evidence, and who decides the case on the facts elicited from that evidence.

If Mr Stratford had made a few inquiries before writing his letter, he might have heard that a special committee is already in existence and is sitting, the object of which is to elucidate the very points to which attention is drawn in his letter, the committee is meeting with the full approval of the Commissioner of Police.

Lastly, both the police and the divisional surgeons dislike "motor drunk" cases more than any others and the

public can be quite happy in the knowledge that no case is taken into court unless the evidence of all kinds is of the strongest—We are, etc.,

PREVENTION OF RHEUMATISM

SIR—Much has been written of late years about the prevention of rheumatism. Prevention resolves itself into the management of the so-called rheumatic diathesis. This only is true prevention. The timely treatment of active rheumatism or of threatened rheumatic breakdown is preventive only in that the more serious sequelae are avoided. What, then, is the most effective management of the rheumatic diathesis? How are we to prevent?

English writers seem to confine their recommendations to the avoidance of exposure to cold and wet. In effect this amounts to very little, especially with the poorer classes, amongst whom rheumatism largely takes its toll. It is hardly more than one would advise for any child, rheumatic or otherwise. The advice lacks definiteness, or it may result in overclothing, which in itself may do as much harm as good. From the above standpoint, I think, we must admit that, apart from the early recognition and treatment of threatening or progressive rheumatic disease—which, it should be noted, belongs to the sphere of treatment rather than of prevention—little, if anything, can be actively undertaken as a true preventive measure.

A different view is taken by American writers—at least by Charles G. Keiley of New York. He urges that the prevention of rheumatism consists in the proper management of the so-called vice of constitution. He says these children "have a poor fat and sugar capacity, especially for cow sugar and cow's milk fat. The nearer the approach to a vegetable and cereal diet, the better for the patient." He forbids red meat, whole milk, eggs, yolk, and artificial sugar entirely, or almost so. He mentions "stomachic grum without other treatment when the sugar and cow's milk fat were removed from the diet." He differs, further, in advocating a cold splash or douche after the bath at bedtime, followed by a vigorous rubbing. As a preventive he gives sodium bicarbonate generally without sodium salicylate, and adds that "lithemic children cannot bear alcohol." "All the measures suggested, without the withdrawal of sugar and fat largely from the diet, are of little avail."

There is a profound difference here. Still, for instance, makes no mention of diet whereas Keiley makes it the mainstay of his preventive regimen. Has the dietetic management of the rheumatic diathesis been neglected in England, or is there a difference between English and American rheumatism? As a school medical officer I would welcome information on this point, for presumably the school medical service is one of the most important agencies through which this prevention may be effected, and according to the English view there appears very little that can be done—I am, etc.,

Gem Street School Clinic
Birmingham Aug 28th

E. H. WILKINS

THE SPAHLINGER TREATMENT IN BOVINE TUBERCULOSIS

SIR—With reference to the annotation on the above subject in your issue of September 12th (p. 488), may I say that (1) several Cheshire agriculturists were approached with a view to investigating the efficiency of the Spahlinger treatment, (2) this committee co-opted medical and veterinary assistants, (3) a representative technical committee was formed, (4) the committee has the benefit of the assistance of representatives of the public health department of the county council and some others working in connexion with that department, and, if the work

develops further, attempts will be made to secure the co-operation of some of the best known scientific workers.

While fully realizing that the preparation was to a certain extent a "secret remedy," this committee feels that it would be doing useful work if the efficiency of the treatment were proved or its inefficiency exposed, in order to dispel the great amount of uncertainty and doubt that exists in many people's minds with regard to these remedies. I would finally point out that this committee did not make the first move, it has no desire to work alone as far as other scientific workers are concerned, and it is I am sure, ready to work in co-operation with any scientific body—I am, etc.,

JAMES BAYLY,
Chairman Bovine Tuberculosis
Committee

Willaton Hall, Nantwich

THE MORBIDITY AND COMPLICATIONS OF DIPHTHERIA

SIR—The answer to Dr. Cameron Kidd's question (August 29th, p. 398) is simply that in the area which he controlled antitoxin may not be given with sufficient frequency on the first or second day of disease—that is, before the case comes under his care. The tables of the McCombie report (which was issued, if my memory is not at fault, somewhere about 1897) show conclusively that the mortality of cases injected on the first day is nil, and that it rises very steeply as each day passes by without antitoxin. The reason of this I believe to be inaccurate interpretation of bacteriological reports by the clinician. Instead of giving antitoxin to every case of suspicious sore throat in a child—which has long been established as the correct procedure—it is quite a common practice to wait for the result of bacteriological examination, and not to give antitoxin if the report is negative.

An experience of twenty-nine years' work in the examination of throat swabs has led me to emphasize that the failure to find diphtheria bacilli in a single swab from an acute case is not only of no clinical value whatever, but is dangerous for the reason given above. For instance, I have repeatedly failed to grow diphtheria bacilli from membrane removed from the trachea in cases of undoubted diphtheria for which tracheotomy was required. On the negative reports from the laboratory of which I am director the following words are printed:

'N.B.—This is a report on the result of bacteriological examination only and does not constitute a clinical diagnosis of diphtheria in the patient nor is it a certificate of freedom from infection.'

I suggest that this procedure might be more widely adopted. As regards the examination of swabs, I think that false negative reports are not infrequently issued owing to undue reliance on specific stains. The morphology of the bacilli should always be studied, and is of major importance—I am, etc.,

London W.C. Aug 29th

A. KENNETT GORDON

COLLECTIVE INVESTIGATION OF RHEUMATOID ARTHRITIS AND ALLIED CONDITIONS

SIR—I also welcome Dr. Logan's suggestion (August 8th, p. 271) as to organization of research in chronic arthritis. Having devoted much time and attention to the subject for twenty-five years at least, I naturally have arrived at certain conclusions. One which stands out very clearly in my mind is that if one is to be successful in effecting something approaching a cure, one must be prepared to continue treatment for an indefinite number of years, using a remedy, amongst others, that is designed to promote the destruction of micro-organisms. In continuous counter-irritation I believe we have such a remedy, and I have proved to my own satisfaction that with due skill and care it may be employed with little or no intermission for ten or more years in an obstinate case.

So far I have never seen any harm that could be traced to the treatment. In my opinion short periods of treatment are of little value—I am, etc.,

Bournemouth, Aug 22nd

WILLIAM J. MIDELTON

Obituary

JAMES MURDOCH BROWN, M.D., F.R.C.P. Ed.,
Formerly Assistant Physician Edinburgh Royal Infirmary

A GENERATION ago the name of Dr. Murdoch Brown was a very familiar one to Edinburgh students, and will recall a short active figure and a quick keen intellect endowed with a genius for the teaching of clinical medicine.

Born in Dunfermline seventy-seven years ago, James Murdoch Brown, after a preliminary training in his father's business, went to Dundee and Flockhart's firm in Edinburgh to complete it. His energetic mind, however, led him to proceed to the study of medicine, and he entered heart and soul into this, having a most successful career as an undergraduate in the University of Edinburgh. Taking his M.B. and C.M. degrees with highest honours in 1874, he was awarded the Pittsler scholarship as the first man of his year. He was not long in building up a first-class practice, and while heavily engaged in private work found time to fill the post of clinical tutor to the university medical wards. He became a Fellow of the Royal College of Physicians of Edinburgh in 1880, and proceeded M.D. in 1897. In due time he was appointed assistant physician to the Royal Infirmary, where his powers of clinical diagnosis had full scope for development, and were utilized to the full by his chief, Sir James Affleck, in connection with the ward teaching.

Eighteen years ago he was laid aside by a serious illness involving a severe operation, from which his recovery was slow. This brought out all his indomitable determination, but he never could resume work. The end came peacefully on September 3rd, soon after his return to Edinburgh from a residence on the Clyde, which he loved so much and where he spent his summer vacations in the height of his practice, sailing his steam yacht and entertaining his friends. incisive in speech, trenchant, upright, and straightforward, he was a keen and fair controversialist, kindly and affectionate, he was a staunch friend, and to his patients he was ever a sheet-anchor.

Dr. Murdoch Brown is survived by his widow and son, his two daughters having predeceased him some years ago.
J O

W J LEIGHTON, M.D., B.Ch.,

Assistant Surgeon St John's Ear Hospital, Manchester.
Dr. WILLIAM JAMES LEIGHTON, who was killed in a motor-riding accident on September 8th, at the age of 42, received his medical education at Queen's College, Belfast, and Dublin, graduating M.B., B.Ch., B.A.O. Belfast, with honours, in 1906, and proceeding M.D. in 1909. He was an active supporter of the British Medical Association since 1912. He had been a member of the Executive Committee of the Preston Division, in 1921 he was elected deputy representative and from 1922 he had been the representative of the Division in the Representative Body.

Dr. F. H. M. MILLICAN (Glossop) writes: Though we were previously students together I first became intimately acquainted with Leighton at Purdyburn Fever Hospital, Belfast, where we were the first medical residents, going in just prior to the opening of the hospital for patients in November, 1906. Shortly after this Belfast was visited by a very severe epidemic of cerebro-spinal fever, and very many patients were sent to the hospital, the first cases were admitted just after Christmas and were diagnosed by Dr. Cudner Robb, the visiting medical superintendent as cerebro-spinal fever, being the first in the city to be so diagnosed. This outbreak brought Leighton and myself very closely together, and resulted in a friendship which remained to the end. He left Purdyburn Fever Hospital at the end of 1907, and took up resident medical appointments, first at the Bellinghrook Hospital, London, and later at Belford County Hospital, he eventually commenced practice in Chorley fifteen years ago. He was a man of many activities, and in intense life had a habit of throwing himself whole-heartedly into a matter he had in mind. He was an honorary member of the staff of St John's Ear Hospital, Manchester, and of Chorley Hospital. He took a keen interest in the welfare of the

latter, and particularly in its reorganization, he attended a meeting of the management called for this purpose the day before his death. Like his father, he was an enthusiastic Freemason, and he took an active interest in medical and national politics. A Conservative by conviction he was essentially open-minded and a man not to be blindly led. He had latterly interested himself in the formation locally of what one might call a "Young Conservative" movement, those who have read *Coningsby* will know what I mean. The heavy burden thrown on the working class by the economic conditions prevailing in the Lancashire cotton area was a matter for which he felt some relief ought to be provided. The necessity of many mothers of young children having to go out to work so as to render the family budget sufficient for living needs was, he thought, fundamentally wrong. He had sized up the evil effects of this upon the health of the community, and he sought a remedy. Like many medical men, he gave a great deal of his professional services without hope of reward, he was always ready to help his colleagues, and during health week he went to many districts to "lend a hand." He had the happy knack of making medical topics clear to the general public, and his services were much sought after. No trouble was too much for him. In character he was outspoken, perhaps brusque, but he was bubbling over with kindness—a real Ulsterman. He was a sincere and loyal friend, and at the Bath Annual Meeting he was delighted to have met again so many of his old friends and acquaintances from the Belfast Medical School. Just prior to his death he spent a holiday in Ireland, and had attended the golden wedding of his parents. To his wife and young daughter, and his father and mother, the sympathy of all his old college chums and medical friends will go out.

Dr. CHARLES EDWARD RYAN of Tipperary, who died on June 24th at the age of 75, was educated in Dublin, where he obtained the diploma of M.R.C.P.I. in 1894, the L and L.M. in 1872, the L.R.C.S.I. in the same year, and F.R.C.S.I. in 1894. He served with the American Ambulance throughout the Franco-Prussian war, and was present at the battles of Sedan and Orléans. He later published a book giving a graphic account of his experiences, including those in the siege of Paris. During the recent war he was associated with the Tipperary Command Depot and Military Hospital. Dr. Ryan was Chevalier of the Order of Louis II of Bavaria, and received the French war medal, 1870-71, and the bronze cross of the French Ambulance Society. He was a justice of the peace for the county of Tipperary, where he carried on an extensive private practice. For nearly fifty years he was a member of the British Medical Association.

Dr. WILLIAM BARCLAY LIVERMORE, who died at Plymouth on August 24th, aged 62, received his medical education at Aberdeen University and the Westminster Hospital. He graduated M.B., C.M. Aberdeen in 1883 and proceeded M.D. in 1918. After a period of private practice at Cleckheaton in Yorkshire he devoted himself to the study of tuberculosis and was appointed medical superintendent of the Didworthy Sanatorium for Devon and Cornwall, which post he held with considerable success for fifteen years. On his retirement he was appointed consulting physician to the institution, in recognition of his constant and zealous attention to the welfare of his patients.

The death occurred on August 2nd, at his home in Beaminster, Dorset, of Dr. THOMAS PALMER DANIEL in his 89th year. Following the profession pursued by his father and ancestors for two hundred years before him, he studied medicine at St Bartholomew's Hospital, obtaining the diploma of M.R.C.S. Eng. in 1858 and the L.S.A. in the year following. He was for two years assistant to Dr. Lovell Drage of Hatfield, and in 1861 he returned to his native town of Beaminster where he entered into partnership with his cousin, William Daniel, in the practice formerly held by their respective fathers. Dr. Thomas Daniel lived and died in the house in which he was born,

on property which has been in the family since the reign of Henry VIII. He was a late vice-president of the Dorset and West Hants Branch of the British Medical Association, and took keen interest in professional matters until illness compelled him to give up work twelve months before his death. He leaves one son, and two daughters, the elder being the wife of Dr W. M. Willoughby, medical officer of health, Port of London, and the younger the wife of Mr A. A. Pim, who carries on the practice in Bournemouth.

Universities and Colleges

SOCIETY OF APOTHECARIES OF LONDON

Dr T. VINCENT DICKINSON, physician to the Italian Hospital, has been elected Master of the Society for the ensuing year, in succession to Dr A. D. Birchley.

The Services

BLANE MEDAL

SURGEON LIEUTENANT COMMANDER LIONEL I. STRECKELL, M.B. R.N., has been awarded Sir Gilbert Blane's Gold Medal, he having obtained a first class certificate at the examinations held in 1925 for promotion to the rank of surgeon commander.

DEATHS IN THE SERVICES

Surgeon Commander Frederick James Burns, R.N. (ret.) died at Hampstead on August 3rd. He was the son of the late Mr James Burns, editor and proprietor of the *Acquy Reporter* and was educated at Belfast, graduating as M.D. in 1884 and M.Ch. in 1885 in the Royal University of Ireland. He entered the navy soon afterwards, and attained the rank of fleet surgeon in 1902. He served for some time on H.M.S. *Terion*. During the recent war he was senior medical officer of H.M.S. *Orion* until invalided for renal disease. His remains were interred at St. Patrick's Church, Newry on August 7th.

Colonel Charles Henry Swaine, D.S.O. Army Medical Service (ret.) died recently at West Palm Beach, Florida, aged 76. He was the second son of the late Dr A. C. Swaine, J.P., of Carrick on Shrumon and was born at that place. He was educated at the Ledwith School, Dublin, where he won prizes in medicine, surgery, and midwifery, and took the L.H. at Dublin and the L.R.C.P. and S. at Edinburgh in 1870. He entered the army as assistant surgeon on March 30th 1872, reached the rank of colonel in November 1902, with over thirty years' service, and retired in September 1905. He served in the yellow fever epidemic in Trinidad in 1881, in the Sudan campaign of 1884-85, with the Nile column, in charge of the Dongola field hospital, receiving the medal and the Khedive's bronze star in Burma from 1886 to 1889, medal with two clasps, and in the final campaign of 1897-98 on the north-west frontier of India, when he received the frontier medal with two clasps and the D.S.O. In 1896 he married Margaret Blakeney, daughter of the late Mr David Gillies of Londonderry, and had two daughters.

Medical News.

THE Westminster Hospital annual dinner will be held on Thursday, October 1st, at Oddino's Imperial Restaurant, Regent Street, W., at 7.30 p.m., under the chairmanship of Dr H. B. Brackenbury.

At the opening of the new session of the Middlesex Hospital Medical School the prizes will be distributed in the Queen's Hall, on Thursday, October 1st, at 3 p.m., by the Hon. Sir Arthur Lawless, and the inaugural address will be delivered by Dr C. I. Lakin on tradition in medicine. The annual dinner will be held that evening at the New Criterion Restaurant, Regent Street, with Sir Arnold Lawson in the chair.

THE opening ceremony of the winter session at King's College Hospital Medical School (University of London) will be held on Thursday, October 1st, at 2.30 p.m. The introductory address will be given by Sir Arthur Keith, M.D., F.R.S., Hunterian Professor of the Royal College of Surgeons of England. The annual dinner of past and present students will be held at 7.30 on the same day at the Connaught Rooms, Great Queen Street, W.C., with Sir Lenthal Cheble in the chair.

THE opening meeting of the new session of the West London Medico-Chirurgical Society will be held in the society's rooms at the West London Hospital on Friday, October 2nd. The chair will be taken at 8.30 p.m., when the president, Dr H. W. Armistead, will read his presidential address entitled "Thirty years of general practice."

At the opening of the winter session 1925-26 of the University of Durham College of Medicine, Newcastle upon Tyne, an introductory address will be given by Sir Humphry D. Rolleston, Bt, K.C.B., M.D., President of the Royal College of Physicians of London, Regius Professor of Physic, Cambridge, in the Examination Hall of the College on Tuesday, October 6th, at 4.30 p.m. The title of the address is "Physic and poetry."

THE opening lecture of the winter session at the Central London Throat, Nose, and Ear Hospital, Gray's Inn Road, will be given on Tuesday, October 6th, at 4 p.m. by Dr William Hill. The title of the lecture is "The practice at the Central in the late eighties: a period of marked advance and foreshadowing many modern improvements in technique."

THE annual dinner of the Society of Medical Officers of Health will be held at the Piccadilly Hotel on Friday, October 16th, at 7.30 p.m., with the new President (Dr G. I. Bachy) in the chair. Among those who have accepted invitations are Sir Kingsley Wood, M.P. (Parliamentary Secretary, Ministry of Health), Sir Arthur Robinson, Sir George Newman, the Right Hon. Sir Alfred Mond, M.P., the Hon. G. I. Stanley, M.P., Sir St. Clair Thomson, Sir Walter Hecker, Sir Dawson Williams, Sir Squire Sprague, Lieut. General Sir W. B. Leishman, Surgeon Vice Admiral J. Chambers, and Dr R. A. Bolam (Chairman of Council, British Medical Association). Ladies are invited and members are asked to give early notice to the Executive Secretary, 1 Upper Montague Street, Russell Square, W.C.1, of their intention to be present, with the names of their guests. A payment of 12s. 6d. for each ticket should be made with application sent before October 10th, after that date the cost will be 15s. each.

THE Fellowship of Medicine announces that a fortnight's intensive course in medicine, surgery, and the special departments begins on Monday, September 21st, at the Westminster Hospital, and on the same day a two weeks' course in diseases of the chest will commence at the Brompton Hospital. Dr C. B. Heald, at the Royal Free Hospital, will give the first of a series of four week lectures on electrotherapy on Wednesday, September 23rd, at 5.30 p.m. A series of lectures on tuberculosis will be given in the lecture room of the Medical Society of London, 11 Chandos Street, commencing on October 12th, at 5.30 p.m. and open to all members of the medical profession. Other courses during October include a special course in diseases of the throat, nose, and ear at the Central London Throat, Nose, and Ear Hospital with an operative surgery class, a course in tropical medicine on Tuesdays and Thursdays, a combined course in diseases of children, a course in urology at the St. Peter's Hospital, and a course in dermatology at the St. John's Hospital. Further information may be obtained from the Secretary, 1, Wimpole Street, W.1.

J.H.L. Sims Woodhead's series of constructive educational health lectures will be given under the auspices of the People's League of Health at the Regent Street Polytechnic on Friday, October 9th, at 6 p.m., and on the following five Fridays at the same hour. Information regarding the lectures may be obtained from Miss Olga Netherlands, 12, Stratford Place, London, W.1.

MR JOHN SCOTT RIDDELL, C.B.E., M.B.O. consulting surgeon to the Royal Infirmary, Aberdeen, has been appointed a Deputy Lieutenant for the County of the City of Aberdeen.

HIS MAJESTY THE KING has graciously accepted a copy of the *Iconography of Andriacus Iscarius*, by Mr M. H. Spielmann, F.S.A. This book, written to commemorate the quarter centenary of the great Belgian anatomist, at the invitation of the academic institutions of Belgium, is dedicated by permission to the King of the Belgians and is published from the Wellcome Historical Medical Museum as No. 3 of the Research Studies in Medical History.

THE British Dyestuffs Corporation, Ltd. (70, Spring Gardens, Manchester), has issued a revised price list of fine organic chemicals for research work, and of indicators, microscopical stains, and medicinal and photographic chemicals.

THE second All Russian Congress for Combating Sexual Diseases was held at Kharkoff this summer, when the following subjects were discussed: the present need of combating sexual diseases in Russia, sex education legislation in connection with sexual diseases, professional secrecy in sexual diseases, syphilis of the nervous system, syphilis of the internal organs, serology of syphilis, experimental syphilis, the question of dispensaries. The meeting was attended by 600 Russians, including medical practitioners, representatives of women's institutes, farm labourers, factory workers, miners, students, soldiers, and young men's associations. The only foreigners present were three German physicians—namely, Drs Jadassohn from Breslau and Paulus and Haenstein from Berlin.

QUERIES AND ANSWERS.

POST HERPETIC NEURALGIA

"C A B" asks for advice as to local treatment of post herpetic neuralgia localized to an area the size of a five shilling piece in a very aged lady who is also the subject of a grave heart lesion.

TREATMENT OF VARICOSE VEINS

DR H. F. GIBSON asks for information on the following points:
(1) Treatment of varicose veins at Bagnoles de l'Orne and its success or otherwise.
(2) Can it be used in cases with ulceration?
(3) Can similar treatment be obtained at any English spa?
(4) Effect of ultra violet rays on varicose ulcer (and veins).

ACNE OF THE FACE

"C I. B." writes in reply to the query by "A B" (September 12th p 498). I have found excellent results from the local application of eucalyptus oil to the spots.

"A E" suggests to "A B" that he should try Biaceborough Spa water for his girl patient with acne. Let her drink a glass of the water twice daily and apply the water twice daily as a lotion to the affected parts. Cysts should be treated surgically.

DR L. J. HONSON (Harrigate) recommends "A B" to adopt the old fashioned method in dealing with acne, of piercing each follicle with a sharp pointed ("Swan") match stick dipped as to its point into liquid carbolic acid rotating the same while expressing the schaeus or purulent contents and in the case of the latter, repeating the action with a second insertion thereby making sure of a due action upon the follicular lining. In addition the following lotion may be used (with perhaps some steaming of affected skin):
sulphur præcip 5j caluminae præcip 5j
boric ad 5j. A light dietary with avoid stimulants is enjoined with daily use with or without sulphur water, and fresh points of acne should be attacked once or twice weekly. Under this treatment even the most obstinate cases of acne have in his experience, gradually subsided and no scars followed.

PLOMBIÈRES DOUCHES

DR K. R. COLLIS HALLIOWAY (Peebles) writes. The following answers to the queries of "G T B" in the **JOURNAL** of September 12th (p 498) may be useful. I have answered the questions in the order in which they were asked and added a few notes.

1 Plombières douches can be given at home. They should only be prescribed in suitable cases. A written prescription should be given for the douches and a thoroughly trained attendant employed.

2 One and a half to two pints of fluid is sufficient temperature of 100° F.

3 should be given in seven days a week are the maximum

4 course of three or four weeks treatment is sufficient

5 A rubber rectal tube should be used the end being lubricated

1 more than three inches is sufficient

6 It should be given very slowly the patient lying on the left twelve to eighteen inches higher than the anus. As a general

rule a Plombières douche should be preceded by an ordinary enema using normal saline solution. This is essential in those suffering from chronic constipation. I frequently prescribe with chronic constipation derive little benefit from Plombières treatment. Plombières douches are generally contraindicated in cases of cardiac disease and in those suffering from myocutaneous weakness. Dilatation of the colon is also a contraindication. In elderly and weakly patients hot external douches, sprays, or baths should not be given immediately after the douche.

DR F. P. DE CAUX (London, W.) also sends replies to "G T B's" six numbered questions.

1 Yes, Plombières douches can be given at home.

2 At least two pints—or as much more as can comfortably be retained.

3 Normal saline at the temperature of the body (99° F.) in container. Sodium bicarbonate may be added if much mucus is present.

4 About twice a week to begin with, then perhaps weekly.

Chronic alcoholics daily until normal stool is produced.

5 Some use a special tube others a stomach pump tube. A large bore tube with one terminal opening is best in my opinion.

6 As far as will easily go—six, nine or twelve inches.

Dr de Caux adds that the position of the patient during administration is all important if saline is to be retained without discomfort.

URETHRAL SPASM FOLLOWING THE PASSAGE OF METALLIC BOUGIE

DR M. W. BOWDIN (London, W.) writes. In reply to "Perplexed" (September 12th p 498), his patient has evidently an organic stricture (due no doubt to gonorrhoea) for which he was operated upon. Presumably he has also an enlarged prostate overlooked, and in consequence the neck of the bladder is easily irritated. A stricture is fibrous tissue, a methyotomy produces a scar (also fibrous tissue). The resiliency of this tissue varies in different cases. On passing an instrument, if large enough, it is gripped by the stricture, irritation is set up and spasm results, often followed by shock, rigor, fever, frequency of micturition, etc. No instrument should be left in for an hour unless inflamed. I would advise "Perplexed" to order his patient to take hexamine for two days before passing the instrument and for two days afterwards. A methyrosesal irrigation with a mild non-antiseptic antiseptic is first given and an instrument, well lubricated is then passed of a size that will enter by its own weight. A size larger is then passed, and left in for one minute. This is followed by another irrigation. The patient is told to have a hot bath and remain in bed for twenty-four hours. Gradual dilatation with a Hollmann dilator may later be tried. The answer to "Perplexed's" query (1) depends upon the amount of infiltration. (2) The calibre of pathological urethras depends upon the amount of infiltration. (3) A bougie should not be left in for more than one minute and the frequency of passage depends upon the rate of contraction and the amount of resilience.

INCOME TAX Car Transaction

"W S S" bought a car in 1922 for £370 and in 1924 sold it for £85 buying a lower grade car for £179. What allowances are due to him?

* First, as an expense of the year 1924 the net amount expended on replacement—namely £179—£85=£94, and secondly, a depreciation allowance deduction from the average profit assessable equal to 15 per cent of £179—say, £27.

Depreciation of Motor Car

"S C" who was advised in our issue of August 22nd that he was entitled to an allowance for depreciation on his present car as well as for the expense of replacing his old car states that the local inspector of taxes disagrees with this opinion.

* We feel convinced that the inspector is in error. The allowance for depreciation operates as a deduction from the average assessment, and is in respect of the machinery and plant (that is the car) in use during the year of assessment. (Conrad Steamship Company v. Coulson [1899] 1 Q B 865). The cost of replacing the old car was a professional expense chargeable as such for the purpose of ascertaining the practice profits of the year in which the renewal was effected. From the equitable point of view both allowances are clearly due—the depreciation allowance because it is a proper charge in respect of the present car and the expense deduction because the expense was actually incurred. To refuse an allowance for car B because the taxpayer had another allowance for car A seems to us plainly wrong.

Salaried Assistant's Expenses

"D G W" is employed as an assistant by his father at a fixed salary. The assessor refuses his claim to deduct therefrom the sums expended on medical books and publications.

* The claim is governed by the rule of Schedule E authorizing the deduction of sums expended wholly exclusively and necessarily in the performance of the duties of the office. However reasonable the expenditure in question may be, it is not allowable unless it is necessary in the performance, etc., and we are of opinion that unless our correspondent is legally bound under the terms of his contract of service to expend the sums in question his claim fails.

Sale of Horse and Trap

"F R C S I" inquires (1) what allowance he can claim for the sale of his horse, harness, etc., for £34 and the purchase of a motor car for £285, and (2) as to any useful hook on income tax.

* (1) At the most he can claim the excess of the original cost of the horse, harness, etc., over the £34 received for the same, but the correct view legally is probably that it represented a loss of capital and that no allowance is due. (2) Messrs Nelson and Co publish a useful little hook on income tax at about 2s 6d.

Interest on Bank Overdraft

"J A A R" writes: I borrow money to buy a practice, and in consequence have an overdraft at my bank. Am I entitled to deduct interest on this from my income tax return?

* Yes or alternatively to make at the end of the year a specific claim to relief in respect of the amount of interest paid to this bank during that year. The latter method might be preferable if "J A A R" has purchased a share in a practice, the profits of which would be assessable in one sum jointly with his partner's share.

Subscriptions

"W M," who is practising in partnership, inquires whether subscriptions to certain specified societies are allowable expenses for income tax purposes.

* If the particular society has arranged with the Board of Inland Revenue to account for tax on the excess of its receipts over its expenses, the whole subscription is allowable, otherwise only that proportion of the subscription can be claimed which was in fact expended by the society on professional purposes.

LETTERS, NOTES, ETC.

"LECHE"

DR PERCY C GARRETT (Cheltenham) writes: In his article on royal banquets in the JOURNAL of September 12th (p. 483) Mr. Murrehead Little speculates as to the meaning of *leche*. It is the French word *lèche*, a slice. Miss M. E. Christie, in her *Life of Henry VI*, says in a footnote to the description of his coronation banquet that "it seems to have been a kind of mould composed of eggs, raisins and dates, spices, and sometimes meat. It was cut into slices and coloured with saffron and other spices now unknown. According to others it was made of cream, isinglass, sugar and almonds." The dish figures in each of the three courses, the most elaborate being "a white *lecho* planted with a rede antelope with a crowne aboute his necke with a chayne of golde." An appendix to this book contains some curious recipes of mediæval cooking, from "Myllk rost" to "Peockkes."

DR RUSSELL V STEELE (Gloucester Gate, N.W.1) writes: The interesting paper by Mr. Murrehead Little on royal banquets in the sixteenth century contains one item in this bill of fare the meaning of which the writer notes is puzzling—this is the word *leche*. Is it not possible that this is the Spanish for milk? French and English words are used in the 'menus' and apparently a Spanish word has found its way among them.

CAUSE AND EFFECT?

DR E. W. S. HUGHES (Halifax) writes to report an unusual gynaecological case. A married woman aged 29, whose second pregnancy was due to terminate on September 7th, consulted him on August 3rd for a "lump" at this vulva. Beyond congestion round this urethra no abnormality was visible, but a vaginal examination showed the presence of a patulous os and a vertex presentation. There was no change in her condition on the next day but six days later Dr. Hughes found the patient dressed to go out for the day though she admitted that the "lump was down." On examination he found a large congested, and oedematous cervix presenting outside the vulva like a senile prolapse, it went back when the patient lay down. He saw a breast pump on the dressing table and found that she had been trying to draw out her nipples, which were completely sunk into this breast as had been the case at her first pregnancy when these efforts had set up a premature expulsive action affecting the cervix only—since the uterus could not descend—thereby elongating the cervix which was automatically sucked down by the vagina, till it presented as a complete pseudo-prolapse. Rest in bed reduced the "lump," and she was delivered quite normally on August 25th. She had used the pump assiduously, night and morning, for three months.

STAB WOUND OF THE BRAIN

MR J. COLLYER ADAM (Public Prosecutor Madras) sends a report of a case in which a man was stabbed with a knife in the forehead with such force that the entire blade, 4½ in. long, penetrated the head. The stab wound was 1 in. long and 1/8 in. broad, it was situated above the inner end of the right eye brow and the corresponding portion of this frontal bone was fractured. The blade had passed deeply into the brain, and survival seemed impossible though the man when admitted to hospital, was talking rationally. The knife was only removed with great difficulty at the end of half an hour. After being treated for forty days perfect recovery resulted.

GALL STONES

DR C. O. ANDERSON (Dunedin New Zealand) writes: In the JOURNAL for April 18th (p. 764), Dr. Dorothy A. Daly writes concerning a case of cholelithiasis in a girl aged 11. This prompts me to record a case in a male aged 9 suffering from intermittent hæmaturia. Radiographic examination showed that the right kidney was large, with a shadow which was interpreted as being a calcareous plaque in a tuberculous kidney. The patient was submitted to operation and during a transperitoneal nephrectomy a gall stone was palpated in the gall bladder. This was removed and subsequently radiographed. This shadow corresponded with the shadow seen on the original radiograph. The stone was over three quarters of an inch in length and about 1 cm. in width.

SHOE DYES

THE danger of using nitrobenzene and aniline in the preparation of shoe dyes is now well known, and Dr. C. W. Muehlberger has contributed to the JOURNAL of the American Medical Association of June 27th, 1925 (p. 1937), details of nine cases of poisoning resulting in this way. Six appear to have followed the use of a shoe dye which contained aniline instead of nitrobenzene as the solvent. The most important symptom observed was cyanosis without apparent cause occurring in a previously normal person. Loss constant symptoms were vertigo, headache, weakness, and nausea. Children seem to be particularly susceptible and possibly there is also an individual idiosyncrasy, as in the case of acetanilide. Chemical analyses of four black shoe dyes are given by Dr. Muehlberger, all these contained either nitrobenzene or aniline. The treatment recommended is to give up wearing the shoes and to keep the patient warm in bed until the cyanosis disappears, oxygen inhalations appear to have been of no value. It is recommended that the manufacture and sale of such toxic shoe dyes ought to be prohibited, and non-toxic solvents substituted for the dangerous nitrobenzene and aniline.

WINDFALL AFFAIRS IN LIGHTNING STORMS

DR M. HENRY (Ilelast) writes with reference to the letter on this subject in the JOURNAL of August 29th (p. 398). During a recent thunderstorm a chimney of my house was hit and a number of bricks and chimney pots knocked down. An aerial is attached to the pots on three chimneys about four yards apart, forming an angle of about 60 degrees. It then goes on some distance and returns, to go through a window. It was the central chimney that was struck. The aerial was not damaged nor was the pot to which it was attached displaced. It was not earthed at the time. No damage was done inside the house, except by soot.

ELECTRO-CARDIOGRAM OF CASE OF PLEURAL EFFUSION

DR G. ANDREW STEPHENS (61, Walcott Road, Swansea) writes: I shall be much obliged if any of your readers can supply me with a copy of an electrocardiogram taken from a case of pericardial effusion. I have made repeated efforts to obtain such a copy, but so far have been quite unsuccessful, although with such a steady constant resistance as is supplied by the presence of the effusion one ought, according to present-day theories to have no difficulty in obtaining one. The point is of great interest as well as of importance and I shall be grateful for any help in connexion with the problem.

THE PARIS-LES CÔTE D'ARGENT EXPRESS

FOR the benefit of medical men with patients who propose to winter in the South we are asked to state that the Paris-Orient and Midland Railway Companies of France, in conjunction with the International Sleeping Car Company, have arranged to run the above train de luxe permanently on and from October 5th next in conjunction with the 11 a.m. departure from London (Victoria Station) a through sleeping car, Calais to Irún, will be attached to this train until November 5th. The Pyrénées Côte d'Argent express will leave Paris at 8.40 p.m. and will consist of *coaches lits*, *Paris-Biarritz*, *Paris-Irún*, and *Paris-Tarbes*, and a restaurant car from Paris to Saint-Pierre-des-Corps. The Spanish railways have agreed to maintain a permanent connection from Irún to Madrid which, besides the usual restaurant car, will include a wagon salon of the Sleeping Car Company.

A HOUSE OF REST

THE "House of Rest" (Maison de Repos) at Montoux for professional men with restricted means who are temporarily in need of rest or change, will reopen this year on November 1st. It was founded some forty-five years ago by subscriptions collected from Britain and from residents and visitors at Montoux. We are asked to say that medical men in stated circumstances requiring a change for health reasons are welcomed. Visitors pay 30s a week, all included. Particulars can be obtained by writing to the station, Miss Goldie whose address at present is 122 Beaufort Street, London, S.W.3 and after November 1st, House of Rest, Quartier de la Madone, Montoux, A.M., France. The honorary physicians to the institution are Dr. Stanley Rendall and Dr. D. W. Samways.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 37, 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 112.

THE BOROCAINES.

A NEW CLASS OF LOCAL ANAESTHETICS

BY

A J COPELAND, M A, M B, D P H, B Sc,
ERNEST HART MEMORIAL SCHOLAR OF THE BRITISH MEDICAL ASSOCIATION
AND

H E F NOTTON, B Sc, A R C S

(From the Laboratories of Pharmacology and Chemistry, Cambridge)

THE object of this investigation was to determine the factors concerned in surface anaesthesia, with a view to finding a local anaesthetic equal in efficiency to cocaine hydrochloride but without its poisonous properties.

The least toxic of the available anaesthetics is ethocaine hydrochloride, this substance, applied directly to sensory nerve fibres, has an effect equal to that of cocaine hydrochloride, but it does not give very satisfactory anaesthesia when injected subcutaneously without adrenaline, and it has little value as a surface anaesthetic either for the eye, nose, or urethra; thus, for the eye it possesses approximately only one twentieth the efficiency of cocaine hydrochloride. So that the essential information required was why ethocaine lost its virtues when applied to a surface.

Experimental Observations

It has been shown¹³ that ethocaine hydrochloride ("novocain") has a strong affinity for sensory nerve fibres, but has very little action on sensory nerve fibrils in the eye. But corneal tissue, while containing a close plexus of the finest non-medullated nerve fibrils, has neither blood vessels nor lymphatics, and investigations were first made to determine whether this factor influenced the action.

When ethocaine hydrochloride is dissolved in rabbit or horse serum or in a solution of egg-white, its power of anaesthetizing the rabbit's cornea is increased twenty times, and becomes equal to that of cocaine hydrochloride. Physical adsorption cannot account for this, since neither gum acacia, pure crystalline egg albumen, cholesterol, glutathione, and the like augment the degree of anaesthesia. If the proteins are removed by boiling or by dialysis it can be shown by a process of exclusion that the enhanced effect is due to alkali present, and this "serum effect" can be simulated by adding to the solution of ethocaine hydrochloride an equivalent amount of sodium bicarbonate. Alkalis have long been known to increase the efficiency of cocaine hydrochloride as a surface anaesthetic. Gios⁶ found that alkali increased the potency of the hydrochlorides of cocaine, ethocaine, alipino, and stavano on frog's motor fibres, and his findings were confirmed by Sollmann,⁸ who extended the principle to include frog's sensory fibres and skin and rabbit's cornea. This increase of efficiency, according to Sollmann, was not observed in intracutaneous injection anaesthesia.

The fact of fundamental importance emerging from observations such as the above, which have been extended by Regnier,¹⁵ is that the surface anaesthetic effect of cocaine and its analogues is not constant, but can be varied

by using different salts of the alkaloid and by adding certain inactive salts to the aqueous solutions used, it is in this that the solution to the problem presented is to be sought. Attention is thus clearly directed to the nature of the components of aqueous solutions of the salts of cocaine and other bases.

When a salt of cocaine formed with a powerful acid (such as hydrochloric acid) is dissolved in dilute solution in water, a considerable proportion of the salt undergoes electrolytic dissociation—that is to say, it dissociates into the electro-positive ion of the base and the electro-negative ion of the acid, a portion of the salt doubtless remains in solution as the salt itself. When a salt of cocaine with a very feeble acid, such as acetic acid, is dissolved in water, a large proportion undergoes hydrolytic dissociation—that is to say, it dissociates into the base itself and the acid, provided the acid is sufficiently feeble, practically the whole of the salt may thus undergo hydrolytic dissociation. Under the various conditions thus indicated, the aqueous solution contains as potentially active components the basic cocaine ion, cocaine base itself, and cocaine hydrochloride itself, the proportions in which these three components are present in the solution can be varied by using different salts and by adding different physiologically inactive salts to the solution. Since no reason exists for supposing that the three forms of cocaine which may be present in the solution are of identical physiological activity, it would be anticipated that the varying surface anaesthetic action of different cocaine salts in aqueous solution should arise from non-identity in effect of those three forms. In order to test the accuracy of this surmise the series of observations recorded in Table I was made. We desire to thank Miss C. Lascelles (Laboratory of Biochemistry, Cambridge) for determining the pH values of the stock solutions.

It will be seen that cocaine hydrochloride solution to which sodium bicarbonate has been added is far more efficient as a local anaesthetic than solutions of other salts of equivalent concentration in base. The pH values of the original stock solutions are given, and it will be seen that the solutions with the higher pH values exert the greater surface anaesthetic action, this result is in accordance with the observations made by Regnier. Now, the solutions of higher pH value are those in which the hydrolytic dissociation predominates, to the more or less complete suppression of electrolytic dissociation and of undissociated salt. The free or hydrolytically dissociated cocaine is thus more powerfully anaesthetic than the electrolytically dissociated base—namely, the electro-positive cocaine ion. It is unnecessary now to discuss the significance of the pH values for the other salts given, and it is not suggested that they have quantitative value.

The indication thus obtained that the electrolytically dissociated basic ion and the hydrolytically dissociated base exert very different surface anaesthetic actions can be readily interpreted. The electrolytically dissociated salt would be expected to be absorbed into the circulation more rapidly than the hydrolytically dissociated base, the latter, being absorbed more slowly, should have more opportunity for exhibiting its surface anaesthetic properties.

TABLE I.—Anaesthetic Efficiency of Salts of Cocaine on Rabbit's Cornea

Drug	Alkaloid Content of Stock Solution in mg/c cm (Ref. Table IV)	Duration of action								pH of Stock Solution	Relative Efficiency (Cocaine Hydrochloride = 1)
		0.05	0.1	0.125	0.25	0.5	1	2	5		
Hydrochloride + sod bicarb 5 mg per c cm	17.85	14	18	21	30+	30+	—	—	—	7.1	10.0
Hydrochloride + sod bicarb equal weights per c cm	17.85	1	8	21	30+	30+	—	—	—	—	5.0
Borate " "	17.85	—	6	10	30+	30+	30+	—	—	5.71	4.5
Benzoate	17.85	—	—	2	10	22	—	—	—	4.9	2.0
Hydrochloride	17.85	—	—	0	2	13	18	30	40+	5.0	1.0
Lactate	17.86	—	—	—	—	5	8	—	—	5.2	0.5
Citrate	17.85	—	—	—	—	0	13	—	—	5.4	0.5
Palcaine											
Borate	17.85	—	7	17	23	—	—	—	—	6.6	4.0
Acid tartrate	17.40	—	—	—	—	—	0	0	4	3.8	0.05

have received practically no attention from chemists, scarcely any of these substances have hitherto been prepared in a state of purity. This is naturally due to the fact that they undergo hydrolytic dissociation in aqueous solution, and thus in general could not be obtained pure by crystallization from water. Lushorn and Uhlfelder,⁵ the discoverers of ethocaine, did indeed describe a crystalline borite of this base, and assigned to it the composition $(C_{17}H_{21}O_5N, 4B(OH)_3)$, but we have not been able to prepare a stable compound of this formula. A definite ethocaine borate may be obtained by crystallizing the ethocaine base with the corresponding amount of boric acid from acetone solution; this compound retains its composition unchanged on crystallization from organic solvents such as acetone, alcohol, and the like.

The composition of this and the other new borites which we have analysed is given in Table III. It will be noted that they are of the type of the imogenic pentaborates described by Atteberg.¹⁸

The borites are conveniently prepared by mixing solutions of the base and of boric acid in either hot or cold acetone, the proportions being those indicated by the composition of the salt, the pure borite crystallizes out on standing. Alternatively boric acid and excess of the base may be dissolved in acetone and the solution evaporated to dryness, after powdering the residue and extracting the excess of base with ether it yields the pure borite on recrystallization from a water-free organic solvent. The details of the preparation naturally differ slightly in the cases of the different bases, but, in general, the borites are obtained by crystallizing the base with boric acid from an organic solvent in absence of water.

Of the borites examined those of ethocaine, betacaine, and alpine alone give stable solutions in water, solutions of the others, in consequence of the hydrolytic dissociation, deposit the free base more or less rapidly on standing. This can be avoided by the addition of a further small proportion of boric acid; such addition, however, depresses the pH value and simultaneously leads to a diminution of the surface anesthetic effect. The three which are stable in aqueous solution seem to be indicated for general use.

Psicaine (the acid tartrate of $d\psi$ cocaine) has been shown¹⁹ to have an anesthetic action on the cornea which is considerably weaker than its low base content suggests, it is as toxic as cocaine hydrochloride. The borite is more than fifty times as powerful as psicaine of equal base strength on the cornea, but it is not more efficient than cocaine borite. This isomer of cocaine, then, has no advantage over cocaine, and it is unnecessary to pursue the subject.

It will be seen (Table II) that the cocaine substitutes are divided for convenience into three groups. In the novocain group, to which new members are constantly being added, it is found that the borites of "G S" and butyn are the most powerful, these substances may be

of some value in ocular anaesthesia, but are unlikely to be of value for other purposes owing to their toxicity, to uncertainty in action due to their precipitation by saline and by tissue fluids, and to the instability of the borates. "G S" is a hydrochloride, it is approximately as efficient as cocaine hydrochloride on the rabbit's cornea; the minimum lethal dose for rabbits by subcutaneous injection of 5 per cent solution is about 160 mg per kilogram, the minimum lethal dose of cocaine hydrochloride being about 75 mg per kilogram.¹²

Tutocain^{12, 13} is less efficient for anaesthesia of the cornea and less toxic than cocaine hydrochloride. The borite of the base has approximately the anaesthetic efficiency of cocaine borite on the cornea, but it is unstable.

Ethocaine in many respects is the ideal surface anesthetic, because its less dissociated salts are practically without toxicity and cause no irritation. The borite is approximately as efficient as cocaine hydrochloride on the rabbit's cornea. It causes slight vascular congestion, and has no effect on the pupil. It does not produce anaesthesia in such low concentrations as do the borites of "G S," butyn, and holocaine, but its advantages in low toxicity, lack of irritation, and stability make this of little moment, since it is at a great advantage when dose, toxicity, irritation, and anaesthetic efficiency are all taken into account. The solution keeps well, and does not precipitate in contact with the tissues.

The following experiments on two rabbits of approximately equal weight indicate its low toxicity.

Rabbit A 1.05 kg received a subcutaneous injection of 2.5 c.c. of a 5 per cent solution of ethocaine hydrochloride (dose = 120 mg per kg). Ten minutes after injection tonic spasms occurred with retraction of the head and rigidity of limbs lasting thirty-five minutes followed by severe clonic spasms lasting some minutes. This was followed by some paralysis lasting eighty minutes after injection after which the rabbit recovered.

Rabbit B 1.10 kg received injection of 2.6 c.c. of 5 per cent ethocaine borite (dose = 120 mg per kg). As a result fifteen minutes after injection the rabbit became quiet for two minutes, after which it was normal. No convulsion or paralysis or other sign of toxicity was observed.

The minimum lethal dose of ethocaine borite by subcutaneous injection in rabbits was not determined, since for a rabbit weighing 1.65 kg even the enormous dose of 20 c.c. of a 5 per cent solution of the borite (1 gram or 600 mg per kg) was not lethal. The animal was paralysed for one hour and the bronchial secretions were increased, but there were no symptoms suggesting stimulation of the cortex (for example, head retraction, twitchings of facial muscles, convulsions), and the corneal reflex was never lost. Complete recovery occurred two hours after injection. These experiments show that the toxicity of ethocaine borite is negligible. The borite, like the hydrochloride, is non-irritant, and 0.5 c.c. of a 20 per cent solution injected subcutaneously into a rabbit's shaved abdominal wall caused only faint bruising on the second day, and thereafter no signs of irritation.

TABLE III—Composition of Borites

Substance	Melt ing Point	Analysis						Stability of Aqueous Solution	Per centage Base in Solid Borate	Solvent Used in Preparation	Formula
		C		H		B O ₃

c 159-160

† The word "stable" indicates that the solution in water does not require the addition of boric acid.

A B Lyons (loc cit) gives 55 per cent

‡ These borates contain 1 molecule of acetone of crystallization

In the nose of the cat, using the perfusion method,¹² ethocaine borate causes congestion of the erectile tissue of the nose, as shown by obstruction to the flow. This is, however, less decided than after butyn, "G S," or cocaine borate, and stimulation of the sympathetics immediately corrected this—that is to say, the vasomotor nerves are not paralyzed. After the use of the other substitutes stimulation of the sympathetics is usually without effect. In other words, ethocaine borate can be given with adrenaline and so cause all the desired anaesthesia together with shrinkage of the tissues.

Cocaine hydrochloride acts equally well both for surface and hypodermic use. Ethocaine hydrochloride, on the other hand, only acts hypodermically, as a surface anaesthetic it is useless, did it act as a surface anaesthetic the necessity for cocaine would be gone. On the other hand, all the borates, like cocaine hydrochloride, act both as surface and hypodermic anaesthetics. It has been shown that this is not entirely due to the pH and the table shows that the different borocaines exert different degrees of surface anaesthesia which cannot altogether be explained by the stability of the different salts, so that a third factor—that of specific affinity for nerve tissues—requires consideration. This factor does not show the wide differences between the different cocaine substitutes that might, *a priori*, be expected, most of the bases are good anaesthetics. Moreover, such comparisons are open to many objections. We have, however, endeavored to obtain some approximate figures by dissolving the bases in castor oil and determining the effect on the eye. Such observations show that holocaine, tuteocaine, and cocaine bases have much the same degree of action. Ethocaine has about one-half the specific effect of cocaine, while other substances such as apothecine produce marked irritation before anaesthesia.

The other salts of ethocaine are shown in Table II for the purpose of comparing H-ion concentration of solution with anaesthetic efficiency. An example of this may be mentioned in further detail.

Experiment—10 ccm of 2 per cent ethocaine phosphate (pH 7.0) was rendered slightly alkaline by the addition of 0.15 ccm of N/5 NaOH the pH being raised to 8.4. The result of this was to double the anaesthetic efficiency so that it equalled that of cocaine hydrochloride.

10 ccm of the solution was rendered slightly acid by the addition of 0.04 ccm of 21 per cent phosphoric acid the pH being thereby lowered to 5.6. The result of this was to diminish the anaesthesia to less than one-tenth that of cocaine hydrochloride (pH 5.0) and to equal that of novocaine hydrochloride (pH 5.6).

The solution (pH 5.6) was now rendered slightly alkaline the pH being raised from 5.6 to 8.4 with the result that the efficiency was raised to that of cocaine hydrochloride (see Table II).

The borate of "523" base has twice the efficiency of cocaine hydrochloride on the cornea, but its toxicity has not been determined.

Holocaine hydrochloride is much employed in eye work, especially in the United States.¹⁰ The borate is extremely powerful, possessing an anaesthetic efficiency on the cornea which is greater than eight times that of cocaine hydrochloride though less than that of the borates of "G S" and butyn bases. Holocaine has the advantage over "G S" and butyn in not being precipitated by saline or tissue fluids, the borate may be useful for ocular anaesthesia.

The borate of beta-eucaine base is the most powerful borocaine, being more than ten times as efficient as cocaine hydrochloride. The toxicity is not yet determined.

Table IV deals with a derivative of quinine, which Dixon has shown paralyzes nerve endings and has little or no affinity for nerve fibrils. Isoamylhydrocupreine bi-hydrochloride is said to produce anaesthesia of the rabbit's cornea in strengths of 0.09 per cent—that is, it should be more than four times as powerful as cocaine hydrochloride. Our experiments do not confirm this, but they show that such quinine derivatives are highly irritant. The borate of this alkaloid was prepared and was found to have about sixty times the anaesthetic power of cocaine hydrochloride. Here, then, is an alkaloid exerting its action in a manner entirely different from that of cocaine and its substitutes, and yet the same principle obtains, the electrolytically less dissociated salts being much more active than the hydrochloride.

It may be well here to state the properties of one borate clearly, for this purpose we select that most generally useful

TABLE IV—Anaesthetic Efficiency of Salts of a Quinine Derivative on Rabbit's Cornea

Drugs	Alkaloid Content of Stock Solution in m.f.c. cm	Duration of Complete Anaesthesia in Minutes Concentration Stock Solution = 0.5				pH of Stock Solution	Relative Efficiency (Cocaine Hydrochloride = 1)
		0.03	0.01	0.05	0.1		
Isoamylhydrocupreine Borate	4.2	0	30+	30+	30+	6.4	60
Bi-hydrochloride	4.2	0	0	0*	0	4.0	?

* Signifies marked irritation

—ethocaine borate. This substance is stable and freely soluble in cold water and Ringer's solution. It does not precipitate proteins like the borates of butyn and "G S." The specific gravity of a 5 per cent solution is high (1.0139), which is useful for spinal anaesthesia. It is non-irritant. It causes anaesthesia of the hum in eye in 2 per cent solutions, the onset being very rapid, and it is equally effective in the mouth and probably other surfaces. Its toxicity is negligible. By subcutaneous injection it is as effective as ethocaine hydrochloride and adrenaline, but not more so. The objection to its use is that it dilates vessels, but this effect can be largely overcome by using adrenaline. In the nose it causes decided congestion whether this effect can be overcome by adrenaline is for clinical observers to decide.

The borates of the local anaesthetic bases possess, as has been shown in the present paper, entirely specific properties as surface anaesthetics, and it may be convenient to class them together under the name of "borocaines." The efficiency of the borocaines as surface anaesthetics depends upon the pH value for the salt in aqueous solution being kept high—namely, on the alkaline side of neutrality. It can be therefore be taken in preparing the salt to ensure that no factor is introduced which will depress the pH value. For this reason the manufacture of the borocaines has been entrusted to The British Drug Houses Ltd., and this firm is prepared to supply the compounds.

CONCLUSIONS

1 The action of a local anaesthetic depends upon the specific selective affinity of its base for nerve fibrils. But the different salts of such a base vary greatly according to the acid with which they are combined. If they are combined with strong acids (that is, those which dissociate electrolytically to a large extent), the salt is relatively rapidly absorbed into the general circulation and is less effective locally—that is, its toxicity is relatively high and its anaesthetic action relatively low. On the other hand, if it is combined with a weak acid which does not electrolytically dissociate to any considerable extent, it is relatively slowly absorbed into the general circulation and is more effective locally—that is, its toxicity is relatively low and its specific anaesthetic efficiency relatively high. Such salts have a high pH value.

2 A new group of local anaesthetics, the borocaines, is described, the members of which fulfil these conditions—that is, they are much less toxic than the original hydrochlorides, from which they can be prepared, but often exert more than ten times the anaesthetic action.

Clinical reports will follow.

We desire to express thanks to the Medical Research Council for the special grant it made for the expenses of this research.

We also desire to thank Professor Sir William Pope for his advice and assistance on the chemical side and Professor W. E. Dixon for help and advice throughout the investigation.

SYPHILITIC NEPHRITIS

BY

G B DOWLING, M D, M R C P,

DERMATOLOGIST, WEST LONDON HOSPITAL. PHYSICIAN IN CHARGE OF
SKIN DEPARTMENT, MILLER GENERAL HOSPITAL. MEDICAL OFFICER,
VENEREAL DISEASE DEPARTMENT, GUY'S HOSPITAL.

WHEN the patient whose case is about to be described first presented himself for treatment the renal condition was not fully investigated. The results of such investigations might have been of interest in the light of his subsequent history, but even without them the facts are sufficiently striking to make them worth recording.

A watchman, aged 56 came to the venereal disease department in 1922 suffering from tertiary ulceration of the soft palate and fauces and from chronic nephritis. He stated that he had been discharged from the police force some four years previously on account of chronic Bright's disease, which had started in 1917, when he was 51 years of age. He had remained in the police force for about a year after the onset, but having been laid up for three months during that period, and being chronically unfit the whole time he was ultimately discharged. After leaving the police force he was able to do light work, but was never really well. He suffered from intermittent oedema of the legs and ankles, and backache as well as giddiness. In 1922 he was laid up for three months with an exacerbation, and the tertiary ulceration of his palate developed at this time. On the day he first attended the department he presented fairly extensive ulceration of the soft palate and fauces. He looked grey and ill, the legs were moderately oedematous and the urine contained a heavy cloud of albumin. A note of his name and address was made on this occasion with a view to having him admitted to the hospital in order to have the renal efficiency investigated and to try and estimate whether he would be likely to tolerate a course of antisyphilitic treatment. Fortunately, in a sense, this turned out to be unnecessary. The Wassermann reaction was strongly positive.

It was decided to start gentle treatment for syphilis immediately and to observe the condition of the urine at each attendance. He returned a fortnight after the first dose (0.3 gram of silver salvarsan) to say that he felt much better in every way. The oedema had practically gone and the urine contained only a trace of albumin. After the second dose he returned to work feeling quite well. That was two years ago. He has never looked back, and has not had another day's illness.

He has had two full unit courses of antisyphilitic treatment—the first consisting of ten doses of 0.3 gram of silver salvarsan, the second of four doses of sulphoxyl salvarsan; the treatment was given in combination with iodide but not with mercury. When I examined him recently he looked a healthy man and had a ruddy complexion. The heart was not enlarged and there were no murmurs. The arteries were not unduly thickened for his age. The blood pressure was 130 (systolic); the lungs were emphysematous to a degree compatible with his age and build. The urine contained neither albumin nor casts. The blood urea was 0.25 per 1,000—a normal figure. The Wassermann reaction was still strongly positive.

But for the circumstance that this patient developed tertiary syphilitic ulceration of the fauces, the true nature of the renal affection would never have been diagnosed. Acute syphilitic nephritis occurring in the secondary stage presents well defined clinical features. It is a rare accident of syphilis. Fournier¹ in his treatise (1906 edition) mentions twenty-six cases. Since our clinic was established (1917) only one case has been recognized. It was published by Rawlins in 1919.

Several isolated cases of acute syphilitic nephritis have been published from time to time. All bear a striking resemblance to one another. The usual time for the appearance of the condition is the second month. More than a third of the cases, according to Fournier, occur during this month, and later observers state that it almost invariably accompanies the acute exanthematous stage of the disease, but may occur earlier or later. Talmann's case, quoted by Fournier, occurred a few days after the appearance of the chancre in a woman of 21. The albumin content of the urine was 32 parts per 1,000, it disappeared without treatment in a few weeks. Fournier quotes a case of his own in the microscopical stage, the albumin disappeared quickly under mercurial treatment. Cases may occur as late as the second half of the first year of infection. Fournier had two fatal cases in this period.

The symptoms do not differ from those of nephritis due to other causes, the patients have oedema and backache, but little or no headache as a rule. Occasionally early anuria is observed. The most striking feature however, is the very abundant albumin. Fournier quotes a case of his own with 110 grams of albumin per litre. Other observers

have found amounts varying from 10 to 100 parts per 1,000. Casts of all kinds may be present—epithelial, granular, and waxy, and some with fatty dioplets. Munk described doubly refractile lipid granules in the casts. Other observers^{2,3} have confirmed this, but Munk stated that he found similar droplets in cases of nephritis due to causes other than syphilis, though less constantly, and it is doubtful whether the observation is of much importance from a diagnostic point of view. Bernard and Widal found that renal permeability was not much impaired according to the methylene blue test. This has been confirmed by other observers, especially in America, with the phenol-sulphonaphthalein test almost normal figures were obtained, even when the damage to the kidneys, to judge by the symptoms and the condition of the urine, must have been severe.

Fournier states that besides the more serious cases of acute parenchymatous nephritis, benign cases, without general symptoms and of short duration, oedema, albuminuria may be the only symptom even when it amounts to 10, 20, or 30 grams per litre. In other cases albuminuria is accompanied by facial oedema, or a little oedema of the ankles. These cases yield easily to treatment, but there may be recurrences. Such cases are not to be confused with the slight transient albuminuria often found in the acute secondary stage of syphilis. Fatal cases, according to Fournier, are rare if the mild cases are counted with the grave ones. Many of them clear up, like the rash, without treatment, and many of them must pass unnoticed. But some of them pass on to the chronic stage or occur in later years.

The most striking feature of the later cases published is the remarkable effect of a single dose of salvarsan or of its substitutes. The effect is instantaneous. The case that attended this clinic in 1917 was a young woman under the care of Dr. Morna Rawlins.² She was pregnant and was in the florid stage of secondary syphilis. The urine contained 7 parts per 1,000 of albumin. After one injection of disodolnagol the albumin rapidly disappeared. She has been seen from time to time and her recovery has proved to be complete.

Elliot and Todd³ published a case in a man, aged 30, with 7 per cent of albumin in the urine, with comparatively few casts and almost efficient permeability according to the phenolsulphonaphthalein test. This case responded promptly to treatment with asphenamin. Day⁴ reports the following very typical case.

A man aged 20 presenting a secondary syphilitic eruption. His symptoms were anorexia and occasional vomiting followed a week later by extensive oedema. The urine was scanty and contained 15 parts of albumin per 1,000 and numerous casts. Improvement began within a few hours of a dose of 0.45 gram of novarsenobillon. It was accompanied by diuresis this continued for a fortnight during which time the patient lost 3 st in weight.

Cole⁵ records the case of a man, aged 26, in the second stage. The urine became solid on boiling; it contained many granular and hyaline casts, but, he states, few compared to the amount of albumin. The excretion of phenol-sulphonaphthalein was 40 per cent in the first hour, 20 per cent in the second. The albumin practically disappeared the day following a dose of asphenamin and totally disappeared on the second day.

Fournier¹ describes the post-mortem and histological appearances in his two fatal cases.

The kidneys were large being increased both in volume and weight. The capsule stripped easily, the surface was a little granular. The cortex was thickened pinkish grey and of firmer consistence than normal. The pyramids were enlarged and congested. The changes were more marked in one kidney than in the other. Both cases presented the appearance commonly known as large white kidney. The histological changes were purely epithelial with fatty degeneration of the lining cells of the tubules. He quotes from Dieulafoy a case with purely epithelial changes, swelling and loss of nuclear staining and degeneration of epithelial cells obstructing the lumen of the tube; the lesions predominated throughout in the convoluted tubules.

Le Plan and Szary⁶ demonstrated *Spirochaeta pallida* in acute secondary syphilitic nephritis.

The patient was a man aged 45 who in the first months of syphilitic infection presented anorexia, headache, digestive trouble, and a large amount of albumin in the urine (12 grams per litre). Mercurial medication brought about amelioration of the condition.

WHEN I read Dr Hollins's paper I planned to verify his contentions concerning the efficiency of raw fresh pancreas in the treatment of diabetes. As soon as possible I conducted a clinical trial on a boy aged 7, who had been receiving insulin for some weeks. On account of some minute incidents—which occurred, by the way, is illustrative of the numerous sources of error which, if not carefully looked for and eliminated, may vitiate any conclusions drawn from such experiments—it took a rather

long period to arrive at a net and unquestionable result. This was thoroughly negative so far as any influence of raw fresh pancreas, orally administered, on diabetic glycosuria is concerned.

Since, in the meanwhile, a number of experiments with negative results have been published by Drs Harrison, Graham and Lawrence, and, on the other hand, Dr Hollins, in a later communication, admits that raw pancreas is ineffective with patients having received insulin, I do not publish the rather long details of my above-mentioned trial, which was performed on a patient of this kind.

Dr Hollins's last contention is that his method of treatment, although ineffective with patients having received insulin, with those that never received this remedy before gives results at least as good as those that may be expected from insulin. I tried to verify this surprising proposition on the first severe patient who had not received insulin that I saw under conditions favourable for such an experiment.

The subject was a boy aged 2½ (Case 606 of my series). The first symptoms of the disease were noticed two weeks before I saw the patient for the first time. Before any treatment was begun, 8 per cent dextrose and a very intense reaction for acetone were found in the urine. The family physician prescribed a moderate food restriction and when the child was brought to me, a fast of twenty-four hours banished the sugar from the urine. I then put the patient on a diet of protein 40 grams, fat 80 grams and carbohydrate 50 grams (fish 60 grams, 2 eggs, milk 300 grams, olive oil 70 grams, 5 per cent vegetables 600 grams, oats 30 grams, nuts 10 grams), which remained constant all during the experimental period except for the day with pancreas, when 30 grams of fish were omitted to partially compensate the extra protein. Pancreas was given only on one day, first because in the circumstances I did not feel justified in further delaying the administration of insulin and also because according to Dr Hollins, glycosuria should disappear within twenty-four hours after the administration of the first dose of raw pancreas.

In this as in my former experiment I personally went to the slaughterhouse saw the animals slaughtered, had the pancreas taken from them within at most twenty minutes after their death and carried the pancreas to the hospital ("Sanatorium per a Diabeticus") in less than ten minutes. The first dose of 25 grams of pancreas was given with lettuce before any other food and not later than one hour after the death of the animal from which it came. The rest of the pancreas was kept on ice in the ice-box, and, in this experiment, a second dose of 25 grams was given at dinner time. Diet glycosuria and pancreas or insulin on the day with pancreas, two days before and five days after, were as follows:

	Date July 1925—							
	6th	7th	8th	9th	10th	11th	12th	13th
Diet								
Protein	40	40	45	40	40	40	40	40
Fat	80	80	85	80	80	80	80	80
Carbohydrate	50	50	50	50	50	50	50	50
Total glycemia (gram)	76.6	19.35	38.2	marked	light	light	light	nil
Insulin (unit)	—	—	50	—	—	—	—	—
Insulin (units) in the injection	—	—	—	15	15	15	20	20

The relations between food, raw pancreas or insulin and glycosuria are more fully shown by the following detailed records for the day with pancreas and the immediately before and after. Under "Glycemia" the colours obtained with the Benedict qualitative test performed with the urine eliminated at the time given are stated. The meals were identical on the three days, except that in the dinner of July 8th 30 grams of fish were omitted to make good for the protein in 25 grams of pancreas.

July 7th		Weather		Pancreas nor Insulin

July 10th 7.30 a.m.					Green

The data obtained very clearly show that, in a patient who had never before received insulin and was on a constant diet of raw fresh pancreas, administered in the form advised by Dr Hollins, and even with an additional dose at dinner time, thoroughly failed to diminish a glycosuria (it was rather increased), which was very quickly reduced to traces on the next day by a very moderate dose of insulin and completely disappeared on the fifth day of insulin treatment.

This experiment on a patient of the acute infantile type of diabetes completes those of Dr Lawrence on two patients of a very different type, all three never treated with insulin before. I fully agree with all Dr Lawrence's essential conclusions and comments.

I fully agree even Dr Hollins's starting assumption that due attention to freshness of the raw pancreas had not been paid in any of the negative pre-insulin experiments is not in agreement with the facts, since at least Allen, Stillman, and Fitz, in 1919,* published a number of experiments of raw pancreas feeding to diabetic patients with negative results, of which they textually wrote: "The pancreas was obtained fresh from the slaughterhouse each day, was kept on ice except during the messenger's trip, and was served raw with vegetables in the form of a salad."

The interpretation by Dr Hollins and his supporters of the facts they have no doubt observed is not correct. All duly controlled experiments, recent as well as ancient, show that the oral administration of raw fresh pancreas has no beneficial immediate effect on glycosuria in diabetic patients.

Thus far, there are no known facts supporting the very faint theoretical possibility that this form of pancreo-therapy might have any kind of delayed beneficial influence in the treatment of diabetes.

DISCUSSION ON
THE PRESENT POSITION OF PATHOLOGY AND
BACTERIOLOGY IN THIS COUNTRY
WITH SPECIAL REFERENCE TO RESEARCH

OPENING PAPER

BY

J. C. G. LEDINGHAM, D.Sc., F.R.C.P., F.R.S.,
Professor of Bacteriology, London University, Chief Bacteriologist,
Lister Institute, President of the Section

TO DAY'S discussion is concerned with the welfare of pathology in this country, a topic which should interest, not only the professional pathologist and bacteriologist, but, I trust, all medical practitioners to whom advances in pathological knowledge that are calculated to help forward the cause of practical medicine make a genuine appeal, whether the opportunity of practical application comes soon, or late, or perhaps not in a lifetime.

The very title of our discussion has a suggestion of spring cleaning about it, as if in fact all was not as it might be in the pathological cosmos, and, indeed, we are here met to take, as it were, the pulso of pathology, and consider carefully and dispassionately what remedial measures, if any, may be indicated. Our committee believed that no more appropriate milieu could be found for ventilating views on this subject than the assembly of the British Medical Association, for it is precisely in connexion with those intimate relationships between the pathologist on the one hand and the medical practitioner and public health administrator on the other that circumstances militating against the due advance of pathology and bacteriology as live and progressive sciences have arisen and clamour a serious and somewhat overdue attention.

The Medical Research Council in their last annual report discussed at considerable length the parts played respectively by physiology, pathology, bacteriology, biochemistry, and experimental medicine in this country in contributing to the general advance of practical medicine during the past five years. They explain how physiology, which admittedly led a secluded life for many years and yet flourished greatly suddenly with the advent of war took the field, and has now become the most trusted and resourceful handmaid of the bedside. The war, we are told, brought the physiologists "to their proper place within the fields of curative and preventive medicine." Again, they say: "The work which has made a real difference to the daily tasks of preventive and curative medicine in the last five years has come from the laboratories of physiology and biochemistry rather than from those of bacteriology and pathology." These would be arresting propositions if they had some real warrant in fact, but, as I shall hope to show later, I believe the compilers of the report have entirely overstated the case for physiology, and have brought to their aid arguments which lend themselves to ready criticism.

The main achievement claimed for physiology in these five years is insulin, which, though it came from Canada, is regarded as the practical outcome of continuous research on diabetes, stretching back forty years. Those modern advances also in renal and cardiac disease, and in the physiology of industrial fatigue etc., redound to the credit of physiology. The honour for these advances it shares, to some extent, with biochemistry—itsself held to be a

child of physiology—and with its aid also there has been developed a new science of nutrition. What is called by the Council experimental medicine has also of late led to advances in practical medical knowledge, and is mainly pursued by the recently instituted units attached to various hospitals in London and elsewhere. When they come to discuss what pathology and bacteriology have done for practical medicine during the same period they can find nothing to place to their credit, even though they take the whole world under their paraview. So far as this country is concerned they attribute this apparent sterility to the fact that the purely utilitarian side of pathology and bacteriology which these sciences derive from their indispensable service to practical diagnosis and therapy has lessened the opportunities of their exponents for contributing to the advance of new knowledge, and has in many cases tended to withdraw from active research life workers who might otherwise have added to knowledge. Grave comments are passed on the practice of the universities in this matter, at least of those universities which maintain pathological and bacteriological departments whose staffs have to occupy themselves with the performance of routine diagnosis on behalf of outside bodies the fees for such services being devoted usually, though not invariably, to the expense of upkeep of the particular department concerned.

This feature of pathological life is probably the one which will be most freely and frankly ventilated to-day by those in a better position than I to speak from personal university or hospital experience. The practice is undoubtedly liable to give abuse, and I agree with the Medical Research Council that immediate reform is necessary in the best interests of pathology. None the less, though reform is clearly indicated, the place which routine diagnosis takes in the training of the professional bacteriologist in the best sense of that term cannot be ignored. This form of training, if intelligently pursued under the careful supervision of the expert, forms, in my opinion, the nucleus of what is perhaps the most valuable asset of the trained bacteriologist—namely, his faculty of judgment and his almost intuitive knowledge of what is sound or unsound in recorded statement. As an introduction to the later and more elaborate training in research method I would regard routine diagnosis as indispensable. When, however, that later stage is reached and actual research is under way, routine diagnosis must no longer be allowed to interfere with the new interests. To make my position clear on this point I would say that in the universities, particularly, any organization on behalf of hospital or public health service that is liable to interfere with the prosecution of research by workers capable and desirous of doing so, merits the serious consideration of the authorities. The main asset of a university is, after all, the research activity and research outlook of its staff.

I take the view that pathological services are more than ever indispensable in the interest both of public health and of general medical practice, and that these services demand trained men who, if of the right stamp, will not be likely to fail in seeking those conditions for their work which will ensure leisure for research. There can be no guarantee, however, of then securing those conditions until by and by medical appreciation of the pathologist's place in the scheme of things has very materially risen. Pathologists and bacteriologists have too long suffered from the clinician's conception of them as purely hewers of wood and drawers of water for their particular benefit. There can be no doubt that the best pathological service can be realized only when ward and laboratory or patient and laboratory are brought as near as possible, and mutual consultation on equal footing can be arranged. Wherever routine work has to be undertaken, very possibly as a whole-time occupation, I do not take the view that inspiration to research must of necessity be wanting in such atmosphere. The many additions to knowledge made during the war by men engaged in the routine investigation of epidemics disproves this, if disproof is wanted. My belief is that research output, even in the apparently unpromising atmosphere of routine diagnosis, might be very greatly increased if the training of men for professional routine pathology and bacteriology were more carefully organized.

Entirely to the practical activities of pathological and bacteriological science has too often been quite haphazard and casual. When the right spirit has been there the result has often been remarkably successful even though the initial training has been meagre, but in my view the time has gone by when we can afford to rely either for routine or for research on the casually trained assistant. Careful selection will always be necessary to secure the best workers for special research as their sole occupation, but I have long felt the lack of any organized movement in this country to train adequately the young graduates who may aspire to take up bacteriology as a profession in life, a profession which, I assume, always involves the obligation to advance knowledge.

At present, though we are far from having attained this desideratum, there are welcome signs of improvement, and I might point to the new courses for the diploma in bacteriology at Manchester and the inclusion of pathology in the Natural Sciences Tripos at Cambridge. A short post-graduate course in bacteriology for the diploma in public health has too often been regarded as an adequate qualification for entrance to professional bacteriology. Bacteriology is a science whose confines have long ceased to be bounded by its purely medical associations. Beginning as a curious department of microscopic botany, it suddenly, under the genius of Pasteur, Lister, and Koch, acquired a place in practical medicine, both curative and preventive, from which it is not likely to be dethroned by any other department of applied biology wherever studied. But bacteriology has now many vastly important ramifications in industrial life, and it is becoming wellnigh impossible for the medical bacteriologist to keep pace with developments in all branches of applied bacteriology. As Sedgwick points out in introducing the *American Journal of Bacteriology* to its readers, bacteriology must henceforth be recognized as a broad and fundamental branch of science co-ordinate with rather than subordinate to the other great divisions of biology. Its study, as Berger insists, involves two aspects: (1) the practical application of bacteriological knowledge to the solution of problems in a special field, and (2) its educational value in broadening one's concept of the various forces and agencies in nature. I hold, therefore, that it is the function of the universities to cater for the graduate aspiring to become a professional bacteriologist by providing advanced instruction in general bacteriology to those desiring it, whether for professional work in medicine or in any other sphere. Due recognition of this subject would be required in any honours course, where it should be at least on all fours with physiology or any other fundamental science. In no other way are we likely to secure a field from which may be recruited workers capable of filling a space, whether in the practical application of bacteriological knowledge or in special research. I trust this aspect of the subject will receive due attention in the course of the discussion, as I am convinced that a greater appreciation of the educational value of bacteriology is essential for securing systematically trained recruits for the bacteriological profession. Posts for trained bacteriologists have greatly increased of recent years, but I am not aware that there has been any corresponding increase in the field of suitable candidates. Believing, as I do, that a training in research methods is indispensable for the professional bacteriologist, I do not think that the available fellowships and scholarships which are offered for this purpose continue to attract young and promising male graduates as they used to do. This is a feature which I view with grave concern. Possibly it may be only a temporary phase consequent on the economic exigencies of the times and the necessity of entering as quickly as possible on a remunerative career.

The forces which have led young graduates in the past to qualify for the laboratory life in bacteriology have doubtless been diverse. The inspiration of the teacher, the organization and general life atmosphere of the university department, have been notorious among these forces, and it is reasonable that the great recruiting grounds of young trained pathologists and bacteriologists have been, and, I think continue to be the Scottish schools. The reason perhaps is not far to seek. Abraham Flexner, in his recently published book on medical education, remarks that

in Great Britain and France, despite their promising start in the eighteenth and in the early decades of the nineteenth century, pathology was, fifteen years ago, dead-house anatomy—a tool of the clinic. Except at Glasgow, nothing resembling an institute of pathology, where even morbid anatomy could be pursued for its own sake, could be found in either country. Autopsies, he says, were abundant, but they were made as a rule by junior members of the medical and surgical staff intent largely upon verifying or upsetting a diagnosis. There can be no question that the intimate connexion which has prevailed in German universities between the institute of pathology and the hospital, the director of the pathological institute being also the hospital pathologist, has fostered the unity and independence of the pathological institute and favoured the prosecution of morbid anatomy and histology for their own sake.

These German pathological institutes, as Flexner points out, and as I know from personal experience, were essentially institutes for the study of morbid anatomy and histology. Routine service to hospital probably restricted the experimental side of pathology, which was cultivated more generally in the departments of physiology, hygiene, and pharmacology. Bacteriology in the German university has usually been associated with the institutes of hygiene, the directors of which have been prominent bacteriologists. This development was primarily due to the influence of Koch, who, in founding with Flügge the *Zeitschrift für Hygiene*, envisaged the enormous importance of the new science of bacteriology to preventive medicine.

In this country, except in Scotland, the development of the pathological institute has been slow, and, in London especially, improvement has been impeded by the numerous vested interests connected with hospital management, but of recent years there have been welcome signs of widening up to new ideas, as evidenced in the separation of chairs of pathology and bacteriology, the development of pathological institutes at Oxford and in the great London hospitals, the founding of new journals, the ample provision of fellowships and scholarships for study at home and abroad, the distribution of grants in aid of research by the Medical Research Council and, may I add, the ever-increasing influence of the Pathological Society of Great Britain and Ireland.

To sum up this portion of my address, it may be said with some truth that in this country—and doubtless elsewhere—pathology and bacteriology have suffered from an undue concentration on the purely practical and didactic aspects of these subjects, both in the matter of undergraduate teaching and in their application to practice in medicine. Unlike physiology, which has remained largely aloof from practical medicine, pathology and bacteriology have given to practical medicine an unstinted and highly unrequited service which unfortunately has entailed a considerable sacrifice of time and brain that might otherwise have been devoted to research. To return under university supervision the best features of routine diagnostic service, whether from hospitals or municipal health departments, will demand a greater expenditure for extra staff, equipment and accommodation, but I firmly believe that the university association is worth preserving in some reconstructed form in the best interests of the coming race of pathologists and bacteriologists and also, may I say, of the particular health or hospital authority enjoying the university connexion.

The form which the reconstruction is to take so that the university connexion may be retained is not for me to discuss. It will I hope receive full consideration to day. The solution will doubtless vary with the local conditions in the university towns.

A corresponding obligation rests on the public health administrator and the general practitioner to maintain a active interest in the general progress of pathological knowledge so that facilities offered by the pathological service may be employed to the best advantage and not be, as they often are, dissipated in unprofitable investigation. A return to war conditions of medical practice would, I suppose, now be unthinkable, but from experience in the late war I feel strongly that the new knowledge with regard to epidemics, the efficacy of new remedies such as therapeutic sera, for example, or of prophylactic vaccines, would not have been ours to-day had it not been for the

compulsory co-operation for a set purpose of all medical units concerned. Some features of the military regime right with advantage be translated to civil life.

Let me refer briefly to the position of research institutes in the scheme of things. The research institute occupies a somewhat different but not essentially different position from that of the universities. Workers in such institutes are generally graduates in medicine or science who are given opportunities for carrying out an approved piece of research under the expert supervision of the staff. All the ancillary sciences that minister to medicine are usually represented in the institute staff, so that the institute forms a self-contained unit. Since also there is open hospital, for the foreigner, the institute fills an important international role. With regard to the work carried out in these institutes, which are not directly linked up with hospital or patient, it has been proved beyond question that experimental pathology and bacteriology, comparative pathology, research in serum therapy and specific disease prevention, supply under the conditions of the research institute a constant stream of problems the solution of which may or may not have their immediate echo in practical medicine. There come times and circumstances, however, when the direct appeal to the human patient becomes insistent, and when that appeal cannot be readily met, or, if met, cannot be adequately controlled by the expert responsible for the initiation of the inquiry and therefore especially interested in its outcome. Both the Pasteur and Rockefeller Institutes have provision for this in the establishment of the research hospital.

In August, 1895, just a month before Pasteur's death, a benefactress came to him with a proposal to construct and maintain at her expense a research hospital of 100 beds for the treatment of diphtheria cases with the new remedy antitoxin, and of persons bitten by rabid dogs with the newly developed immunization methods of Pasteur. Thus was founded the first research hospital, the perfectly natural tribute to the achievements of a single man of science working in the interests of suffering humanity.

In 1907 the board of directors of the Rockefeller Institute, which had been founded in 1901, were invited by Mr. Rockefeller to submit a plan "for an important extension of the field of medical research—namely, a means of studying disease in its clinical aspects under conditions as near as possible to laboratory standards of exactness and efficiency." Thus was founded with ample funds the Rockefeller Hospital, which has been an invaluable adjunct to the institute, though in many respects it is by its constitution a self-contained unit, possessing its own clinical, physiological, and pathological laboratories. I cannot here labour the advantages which such research hospitals can confer on the institutes to which they are attached. I shall just say that at the Lister Institute we have a side ready for a research hospital when the necessary funds come along.

It may be asked, however, how far the ideal of the research hospital is met by the new unit system. Certainly the unit system should approach to this ideal, but it must be remembered that fundamentally the unit system is a link in the pedagogic chain. Consequently the freedom that the research hospital gives to select cases for study, and to retain them for as long as may be necessary in the interest of the problem under investigation, cannot be realized under the unit system, not owing to the distractions of the pedagogic side, nor the full ideal of the research hospital is realized. With the research hospital I would associate the experimental farm and would take this opportunity of alluding to the possibilities afforded by institutions of his kind under the Medical Research Council, the Wellcome Research Laboratories, the Boards of Agriculture in England and Scotland, and the new department of comparative pathology at Cambridge. The special requirements of comparative pathology will, I trust, be duly considered in the following discussion.

I pass to consider some remaining points relative to the actual progress of pathology and bacteriology in this country in spite of the handicaps to which I have referred.

The Medical Research Council, in order to press certain perfectly reasonable measures of reform, have attempted an estimate of the achievements over a short period of

pathology and bacteriology as compared with those of physiology and biochemistry. In my opinion they have not done wisely in attempting such assessment, and some of the arguments adduced to support their points are, in my view, founded on irrelevant or inaccurate statement. At the close of the report they have given expression to the possible fallacy involved in estimating achievement over a short period, but they have nevertheless done so, and the repentance comes rather belated.

It is clear to me that the Council find themselves on the horns of the God and mammon dilemma. They have seen the practical achievements of insulin—after forty years of effort—they have noted the practical issues of the new science of nutrition and the application of experimental biology to questions like industrial fatigue. They see the physiologists are now becoming practical people. They then reflect that too much practical application, which may involve purely commercial considerations, tends to stultify research and point the finger at pathology and bacteriology. Bacteriology, in their view, has just been groping about for new weapons of attack, the old ones having served their day. So it has, and possibly in less than forty years it may succeed in solving the problem of cultivating the invisible viruses (if it has not done so already), but bacteriology has been by no means at a standstill either in this or in other countries. When the Council say that not one of the causal organisms of the common communicable diseases has been discovered in our university laboratories, it must be remembered that neither have any been discovered elsewhere. The reference to discoveries by British workers abroad in connection with malaria, kala-azar, sleeping sickness, etc., has little relevance to the present issue, while the statement that the work actually done in our university laboratories was not such as to attract notice and interest in other countries has a most ungenerous savour even if it were a true remark, which it is not. The Council forget that the individual research worker can rise above such things as university organization and ideals.

In recent years we have seen new and promising developments in the preventive medicine of diphtheria and scarlet fever, and gained a vast amount of new knowledge relating to typhus fever, trench fever, neurotropic viruses, anaerobes, and spirochetes, and now, let me add, of cancer. In addition, general bacteriology is being quietly and successfully pursued in many laboratories, and fundamental questions such as the factors which control the growth and variation phenomena of bacteria are being attacked. The solution of these problems may affect profoundly our conception of the nature of the relationship between host and parasite—that ever insistent field of inquiry of pathologist, bacteriologist, and epidemiologist alike.

If bacteriology fruits in five years to throw up an attractive flower, Heaven knows that in the past forty years it has thrown up many. Let it rest for a while in the apparent slumber of growth and rejuvenescence, working out anew its fundamental problems in activities which do not attract, perchance, the attention of the superficial observer. [This was written a few weeks ago. It may be that the attractive flower I speak of has already blown.]

Let me, lastly, say a word on the question of terminology. One constantly meets with that curiously artificial classification of research workers into physiologists, pathologists, bacteriologists, biochemists, and exponents of experimental medicine. Physiology, as the study of normal function, tries to express its phenomena in terms of physics and chemistry, while pathology, as the study of abnormal structure and function, attempts the same, with perhaps less faith, though its methods are no less precise than those of physiology. Much of what is called modern physiology is frankly experimental pathology, and, as to its achievements, surely the knowledge of normal function which the physiologists have gained has come mainly from the study of induced disease. Bacteriology, initially a purely biological study, became suddenly a department of experimental pathology, which, in the main, it still is, but many of its numerous offshoots in industry and agriculture are essentially biochemical in character.

Modern biochemistry dates its chief impulses from Pasteur's fermentation studies the work of Emil Fischer

and the developments which took place towards the end of the nineteenth century in the study of physical chemistry. Many of its problems, especially in industry, biochemistry shares with bacteriology. The new science of nutrition is equally the outcome of Hopkins's physiological researches on growth and of the earlier observations of pathologists like Holst, Eijkman, Braddon, Fraser, and Stinton. There is no historical warrant for fathering biochemistry on physiology. Research is discontinuous. One goes a little forward only to recede a little less and then again advance, and in the biological sphere no one can tell from what practical department a new weapon of attack may come.

The biological research worker is becoming increasingly difficult to label, and possibly it may in the future be found more convenient to drop these terminological intricacies and employ some more comprehensive label which will express that interdependence of all the biological sciences on which alone hangs the future progress of research.

GENERAL DISCUSSION

Professor M. J. STEWART (Leeds) said that he found himself in sympathy with the views which Dr. Ledingham had expressed. The training of the pathologist was strictly relevant to the subject of the present discussion. The academic duties of a university pathological department included not only the instruction of students, undergraduate and graduate, and the prosecution of research, but also the training, in all branches of their work, of future pathologists. Most of the latter must, by force of circumstance, become either hospital pathologists, bacteriologists to health authorities, or consulting pathologists in private practice, and for their proper instruction and training an abundant, steady supply of fresh pathological material was an absolute necessity. Especially was this so in the field of morbid anatomy, where proficiency in diagnosis could only be attained after years of training and experience. It might be argued that men of this class should receive their training, or at least their later training, in hospital and public health laboratories, they should certainly receive some years of training in university laboratories, where they would not only have the spirit of disinterested inquiry and research inculcated from the earliest stages, but would be able to maintain contact with and to receive intellectual support and encouragement from men working in other subjects and faculties. They would also have the resources of a well founded library always available for immediate reference. A primary difficulty in connexion with the training of pathologists was that in most cases the candidate started on his medical undergraduate career with only the haziest notion of his ultimate destination. Late in his course, or perhaps after graduation, he found himself attracted by the charms of pathology or bacteriology and later still learnt how inadequate had been his preliminary training for this work. Hence was little or no difficulty about his requiring in time satisfactory working knowledge of these sciences, which he lacked was that broad, fundamental training in mathematics, physics, and chemistry which would enable him to tackle with success the great problems of disease still awaiting solution. Physiology scored in that a student might study this subject intensively before starting on the task of the later medical curriculum, and might even take a course therein without necessarily continuing the medical course. A similar position was being attained by bacteriology. In Leeds, for example, there was now offered a four years' course leading to the degree of bachelor of science with honours in bacteriology. He doubted, however, whether pathology could be so studied with advantage—much as in end in itself, and divorced from the clinical side. That was not to say that the study of the subject might not be commenced in the pre-clinical years, and one enriched with sympathetic interest the important experiment now being made at Cambridge of placing pathology among the subjects for Part II of the Natural Sciences Tripos. It was the fashion some twelve or fifteen years ago to deem morbid anatomy as a worked-out subject indeed, its "passing" was duly announced, and one gathered that the whole future of pathology lay in the hands of the bacteriologist and the chemist. That was very far from

the truth. Instead of being at the end they were still only a little way past the beginning instead of dropping the subject because there was nothing more to be discovered, they were merely on the outer fringe of a very big and most difficult field of study. Of recent years, however, there had been a definite revival of interest in the subject less striking, perhaps, in this country than abroad, but even here sufficient to act as a valuable incentive to further effort. Might it be that one of the factors responsible for the decline of interest in morbid anatomy a few years ago was the position occupied by normal histology in many of their medical schools, probably as a direct result of the increasing interest in experimental physiology and in biochemistry? In most schools, he imagined, the subject was still taught under physiological auspices, in a few under anatomical, and neither physiologist nor anatomist, with a few notable exceptions, seemed at all anxious to hold the baby. Was not the time now ripe for the institution in all their universities of departments or chairs of normal histology, or at least for the appointment of senior members of anatomical or physiological staffs, whose first duty should be teaching and research in normal microscopic anatomy? The critical examination of the present position of pathological and bacteriological research in British universities in the last annual report of the Medical Research Council had already been referred to by the President. While there was undoubtedly much justice in these criticisms, he did not agree with the wholesale ban on routine work there pronounced. The value of such work in the training of young pathologists had already been mentioned, but in the case of morbid anatomy the "research value" of routine work must also be borne in mind. In illustration, if such were needed, one might refer to the admirable work of Nicholson of Guy's on the histogenetic relationships of tumours, the tissue heterotopias, and allied subjects, and of Masson of Strasbourg on the histology of tumours. From the point of view of the encouragement of research it was the conditions under which the routine work was done which mattered, and here it had to be admitted that things were not all they might be in many universities. It should only be permissible for a university department to undertake work of this kind provided that the amount per individual member of staff was not excessive, and that adequate accommodation was available. It should also be possible to free members of the staff entirely from routine work when occasion required, in order that they might concentrate for the time being on special lines of research. These conditions were on the way to attainment in most of the university centres where routine work was done. The Medical Research Council's report made no distinction between the routine work of the hospital and that of the public health service, yet it was, he thought, generally admitted that work coming within the latter category was of much less value than the other for purposes of teaching and research. Possibly it required to be dealt with on different lines. After reading the report's whole-hearted condemnation of the practice of applied pathology within the universities, it was pleasing to turn to the section which dealt with physiology, and to find that what was sauce for the goose was by no means sauce for the gander. "During the war," they read, "the pressing need for bringing the best physiological knowledge to the aid of sailors, soldiers, and workers in their exposure to every kind of violence, hardship, and physical stress, brought the physiologists increasingly to their proper place within the fields of preventive and curative medicine. This closer union brought many benefits to practical medicine, whether military, civilian, or industrial. Equally it brought benefit to the physiologists for the challenge made by practical problems, here and in so many other instances, so far from taking men away from the academic pursuit of knowledge for its own sake, was found to freshen their interest and to suggest new clues for further pursuit by theoretical inquiry." He concluded with a plea for a much enlarged side of the work—that part of it which surgeons especially, but even some pathologists, seemed fond of designating "dead-house pathology." The pathology of the living, as it was called, had become something of a fetish in these days, but while admitting as fully as possible the enormous value, for research purposes, of the pathological investigation of the living subject, he reminded his

audience that, after all, the *post mortem* room still provided an invaluable and almost inexhaustible field for original research.

Professor CARL H. BROWNE (Glasgow) said that Dr Ledingham had made a very comprehensive survey of the matter, and that his conclusions would meet with general acceptance by practically all who were in a position to judge. The quality of the pathological and bacteriological work which was being done in this country would bear comparison with that done elsewhere. British workers, however, as a rule, had been disinclined to utter generalizations which they believed might be premature, and this, coupled with a striking absence of the polemical spirit, had probably been mainly responsible for the small degree of publicity which their work had obtained in this or other countries. There were three points arising out of the subject for discussion on which he desired to lay special emphasis: (1) the training of the research worker, (2) the facilities for research, and (3) the endowment of research. To begin with, however, the question of bacteriology, considered separately from pathology, required brief attention. The investigation of bacteria for their own sake, and apart from any application, for example, to problems of agriculture, disease, etc., was eminently desirable, and there could be little doubt that many questions would be elucidated by such a study, but its pursuit was only beginning to be seriously undertaken, and the problems did not concern pathology more than botany and certain other sciences. He would therefore consider bacteriology solely in relation to disease or, as it might be termed, medical bacteriology. Here one was, of course, speaking of the training of talented individuals, and not of geniuses like Pasteur, since for these it was not possible to legislate. It was self-evident that pathologists and bacteriologists must have a medical training in order that they might be capable of appreciating the problems with which they had to deal. If, in addition, a degree in pure science had been taken, an excellent basis would have been provided, and the invaluable knowledge of how to conduct an experimental inquiry would have been gained. A working knowledge of French and German was essential. The course of study for an honours degree in science occupied with advantage four years, and included natural philosophy, physical and organic chemistry, anatomy and physiology, in addition to the principal subject of pathology with bacteriology. The principal subject, which was studied for three years of the course, occupied the whole of the time of the final year, the latter being devoted to research in some special branch of pathology or bacteriology. A similar course, in which some other principal subject was taken—for example, chemistry (organic or physical), physiology, or natural philosophy—would probably provide a training at least equally valuable. These schemes of courses were cited, by way of example, from the regulations of the University of Glasgow, but similar courses were followed at other universities. But besides a knowledge of the clinical aspects of disease, and as full and varied a scientific training as possible, a prolonged apprenticeship was required in a pathological department, preferably, to begin with, in one which combined both teaching work and routine examinations for a hospital. Assistantship in such a department, on the one hand, imparted familiarity with the natural history of disease and the correlation between pathological findings and clinical phenomena, on the other hand, teaching duties implied an intimacy with the subject in its broadest aspects. Such experience, acquired under the guidance of an able chief, was an excellent, and probably the best, foundation for sound research work, which would, of course, be carried on also at this time. It was to be noted that in this training no distinction should be drawn between the more purely bacteriological side and the pathological aspect of the work. It was a misfortune that medical bacteriology in hospitals was sometimes carried out by a separate staff housed in a department distinct from that of the pathologist. The young bacteriologist brought up under such conditions might run the danger of becoming a mere identifier of organisms. It was apparent, then, that the definition which he attached to medical bacterio-

logy was that it constituted that branch of pathology which dealt with infective diseases and their causation.

In the early period of post-graduate work it was of the greatest advantage to the worker to hold for several years a whole-time research fellowship. It was usually most preferable to hold this before entering on an assistantship, since the latter post was a more or less permanent one, and if relinquished could not perhaps be readily taken up again. But there was little doubt that the best results would be secured by the holder of such a fellowship having undergone several years' assistantship beforehand, so that in that way the special problem of the research would be surveyed with a better general perspective. In practice, however, the point was perhaps not very important, since the worker would be influenced by the criticism and encouragement of the other more senior members of the laboratory, and in this way he would gain his most valuable training in outlook and in experimental method. He regarded this period of work as an exceedingly valuable part of the investigator's training, and would prefer to omit the degree course in pure science rather than to cut out post-graduate study, which was undertaken apart from the influence of impending examinations.

Pathological problems were presented in their truest and most concentrated form to the pathological departments of hospitals. Where these laboratories were combined with the teaching departments of the universities, particularly good opportunities were afforded for the training of pathologists. It followed that the workers who had experience as to the nature of the problems should also have facilities for attempting their solution, and, therefore, that research work should be in active progress in these departments. It must be recognized, however, that a general miscellany of staffs would be required in order that this plan might come into effective operation. He would not regard it as excessive if, as had been recommended, every member of the staff of every pathological department had at least half of his working time free to devote to research work. Further, this free time should belong to each worker by right, and should not depend on the award of any form of terminable fellowship. In all such matters the arrangements should rest with the chief of the department, on his spirit and judgement depended the success of the department as a centre of research. The wide adoption of the custom of the sabbatic year was highly desirable also.

As regards infective diseases, it was, of course, at the fever hospitals that bacteriological and pathological research of the highest importance remained to be done. It was, however, with the greatest concern that one saw still so great a neglect of sustained investigation in these hospitals throughout the country. The problems of disease as presented there were among the most vitally important to the community. For in these hospitals one had to deal with acute infections which crippled or cut short young and active lives. The subjects attacked by such diseases were capable of vigorous reaction, and the problem of aiding their resistance appeared to be among the most hopeful of those which awaited solution. But there was as yet little or no provision of trained pathological and bacteriological investigators at the fever hospitals, and the important research work which ought to go on at these institutions was left virtually untouched. The establishment of active and continuous research work at all the large fever hospitals would mark a great advance, and was likely to yield results which would prove of the utmost value to practical medicine.

It was not intended to imply, in what had been said, that institutes for research pure and simple did not play an extremely valuable part. But they would exert their most beneficial influence by attracting the more experienced workers. It was worth mentioning in this connexion that the pace of research work probably could not be hurried on indefinitely, and that it was vain to hope that a colossal institute furnished with very large numbers of workers and with huge material resources would in a short time solve a proportionately large number of problems. Time was an essential factor in research, which would not yield all its best results to methods of mass

production. A closer association of research in animal and human pathology was most desirable. Few university departments had facilities for the adequate maintenance of considerable numbers of larger animals. Such animals were more and more necessary in the elucidation of human pathology, and the experimental work of the pathologist in the past had probably suffered greatly from being so much restricted to small rodents. Therefore the participation of the universities in veterinary training and research would without doubt confer high mutual benefit.

Even when adequate staffs were provided there still remained the need for the materials required in research. Although it was now admitted generally that research was one of the functions of a university, the provision for the material needs of research on a satisfactory scale did not appear to be very seriously considered by local bodies. The Medical Research Council had given almost inestimable assistance by paying for both personnel and material. But the Council, apart from the National Institute, were concerned with individuals and with particular schemes of research work rather than with the financing of departments. Also no other body, so far as he knew, made grants for research except on a personal basis and for particular schemes of work, and the period of the support was strictly limited. The financing of laboratory expenditure on a generous scale was essential, however, if continuity of research work was to be secured. And it was to be remembered that the kind of work which was worth doing was largely of a nature which might proceed for years without affording striking results, and even without furnishing materials for honours theses to candidates for doctorates. Such work could best be aided by local endowments, and research endowments of this kind were an essential complement to the endowment of professional chairs. Without the former the latter were not likely to produce the anticipated fruits of first-class research. It was particularly important, however, that such endowments should be secured without the fettering condition of their being applied solely to the investigation of some particular specified problem or disease. No benefactor was likely to be wise enough to know what investigation could be most profitably pursued even a year hence. Here as throughout, one must trust the competent investigator.

Dr J. A. BRAXTON HICKS (London) said that the ground had already been so well covered by the previous contributors that, as the last contributor to the opening papers, he would confine his remarks to but two aspects which greatly affected pathological research as seen in teaching hospitals of university standard and even in large university departments of pathology. The first factor militating against efficient and sustained research was the excessive burden of teaching and other routine duties too often imposed on responsible directors and senior members of pathological departments. This factor was a variable one in different institutions, but there was no doubt that it existed to a certain extent in all. They had all been informed by the sponsors of the large clinical unit system that here there was a solution of the problem as touching effective research into clinical and even the profounder problems seen in disease. It was in practice a fact that such was not the case and that the directors and workers themselves found their efforts still hampered by the necessity of undergraduate and post-graduate teaching. He did not think the solution of this problem was the divorce of teaching and research, because it was to his mind essential for university discipline that some instruction should come from the senior members of a university department. The solution was, as Professor Browning had suggested, the provision of much larger staffs, and therefore this implied as a consequence the better endowment of pathological departments. For too long had those responsible for university and hospital administration regarded pathology as the Cinderella of the three sisters, medicine, surgery, and pathology, and had often thought it right to expect that "research" should commence when the ordinary day's work was done. Indeed, this was reflected in the popular idea of a research worker as one who wrung secrets from reluctant nature by copious consumption of the midnight

oil. The second factor, and one which would continue to hamper research to an even greater degree in the future, was the absence of a good supply of suitable young workers in the departments of pathology. Largely this was economic, for the remuneration offered to young men anxious to take up bacteriology and pathology could not be considered adequate and indeed hardly constituted in many instances a living wage. Previous contributors to this discussion had expressed views as to the value of routine work, even work of an admittedly routine "commercial" type, such as public health diagnostic work. Personally he held that routine work of any sort was of the utmost value in the proper training of a bench worker. A man in training to become a valuable worker should know the essentials of everything that pertained to his job. Thus a bacteriologist should know the essential facts about media making when he commenced his career, and so on for other branches of pathology, otherwise how could he put his finger on possible factors governing his experiments if he did not know the fundamental factors? Again, a young man set to do routine work over a certain period of time needing skilled technique required "bench sense" and could be known by his work to be a reliable worker. Once they had a reliable worker to whom they could detail certain lines of investigation that might arise in any department, that worker would quickly evolve ideas of his own arising out of that line of investigation, and once they had a man who could evolve, as it were, "side lines" such as those, they had, he thought, a research worker in being. He personally, therefore, regarded routine work as the best "kindergarten" for the research worker, where this work was carried on under university conditions that workers had every opportunity of viewing pathology in its broadest sense, and did not necessarily find himself labelled as a morbid anatomist, bacteriologist, biochemist, etc., though he might show a certain aptitude for some particular subject which it was the duty of the director to encourage and foster. To summarize his remarks, it was essential, first, that the trained laboratory worker should have adequate time at his disposal for research, and that could only be done by increasing the staff of the departments of pathology, and, secondly, that young men should be encouraged to take up the various branches of pathology by being adequately remunerated. These two conditions necessitated a proper endowment of pathology. Further, they must not divorce teaching from research, nor routine work from the departments of pathology, for teaching was good for discipline, both in the teacher and in the disciple, while routine work trained the future research worker. And last, but not least, university experience should broaden the outlook of the laboratory worker in all branches of pathology.

Dr J. A. ARKWNIGHT (London) said that at first sight it appeared futile to discuss whether physiology or pathology was the more fertile field to cultivate, since the distinction between them was arbitrary and difficult. Such comparisons had, however, been made recently, as recalled by the President. Pathology was concerned with morbid structure and function, and physiology was also concerned with function, but the distinction was usually made that the latter was concerned with function in a state of health only. As had been pointed out, however, physiology had very frequently to draw its conclusions from morbid states which might even have been intentionally induced for the purposes of experiment. The question how far pathology and bacteriology should be studied in isolation apart from practical human affairs seemed to be determined in the main by what might be called opposing centrifugal and centripetal forces. There were a number of practical objects besides medicine which led to the study of bacteriology, and each, approaching this science from a different angle, contributed to the sum of knowledge. Clinical medicine and hygiene (human and veterinary) must always remain at the centre of medical science. The subsidiary branches had so tumbled off from this centre on account of the uncollected difficulties of applied medicine, due to its extreme complexity and the many variable factors involved. In order to resolve the problems into simple terms recourse had been had to the dead house, and attempts had been

made to analyse disease organ by organ and tissue by tissue, dead or alive. To make this involved research easier and more hopeful of clean-cut answers, the student had sought to obtain more uniform conditions as a foundation, and had tried to reach less variable standards in the more stable states of health by studying what appeared to be the basic science of physiology. The difficulties, however, were still great, and, continuing the process, physiology had resolved itself so far as it could into mechanics, biochemistry, colloidal chemistry, and physics, which now very largely constituted what was known as physiology.

The other great force which controlled the course of development of the medical sciences might be called the centripetal force, which drew the auxiliaries to the main body and caused the workers to turn to the needs of clinical medicine and hygiene for their inspiration and justification. In a sense, no doubt, it might be said that a science like bacteriology could stand alone and be its own justification. Nevertheless, he thought that human beings usually needed a more definite aim or goal, near or remote, to justify the course they were pursuing, and to silence the sometimes insistent demands of "Cui bono?" He believed this was especially the case in early life, when energy was greatest and careers were being determined.

Medical problems, though not alone in this respect, had a very wide and powerful influence in this sense. The more intimately pathology and bacteriology could be linked to practical medicine, without a serious sacrifice of the necessary specialization and unhurried research, the better for both departments. That university departments of pathology and bacteriology had found it desirable to sever their connexion with hospitals or public health work must depend on temporary conditions, such as the lack of appreciation by public health authorities of the help which science could and should render to hygiene. The severance was hardly likely to be permanent, though the funds and other conditions for the union might for the time not be satisfactorily provided by the public health authority or by the university. The only justification for this divorce from the public health point of view would be the provision by the authority of laboratories so well equipped for wide and thorough research in pathology, bacteriology, and the allied sciences, that they constituted in themselves scientific institutes of university standard. As the scientific theory of preventive medicine in relation to pathology and bacteriology became more fully thought out and expanded, it seemed probable that a correct alliance of the hygiene departments of universities with these sciences and the public health service would appear.

DISCUSSION ON FOOD MANIPULATION IN RELATION TO HEALTH

OPENING PAPERS

I—WILLIAM G. SAVAGE, B.Sc., M.D. LOND
County Medical Officer of Health, Somerset

We are all aware that the applications of scientific knowledge and the difficulties of feeding a rapidly increasing population have resulted in a great increase in the extent to which our food supply is presented for consumption, not comparatively unchanged as in nature, but materially modified and altered. It is of great practical importance to consider very carefully the extent to which such changes in our food habits are of importance in relation to the health of the nation, to decide the amount of oversight which should be exercised over the methods employed, and in particular whether any check should be enforced in regard to the extent to which food is allowed to be manipulated. All three considerations are of great importance, and will, I hope, be thoroughly discussed.

It is a mistake to imagine that food manipulation is a modern phenomenon, it is attached as man's civilization,

but the extent and form of it is largely modern. Indeed, the art of cooking food is itself a form of food manipulation, and as such cannot be neglected in regard to its influence upon the foods so treated. It is unnecessary to describe in detail the different forms of food manipulation, but as a basis for discussion it is convenient to outline the different types in relation to the objects in view, or unintentionally achieved.

1 Manipulation to Preserve Perishable Foods.—This is a very valuable objective since it not only enables seasons of plenty to be used to balance seasons of deficiency of food production, but it allows foods plentiful in one area to be made available for those in another in which they are absent or deficient. The methods employed are preservation by the action of cold, putrid or complete sterilization by the action of heat with subsequent exclusion of air (canning and bottling), drying to eliminate water, the addition of chemical substances (preservatives) to inhibit bacterial growth.

2 Manipulation to make the Finished Article More Digestible or More Palatable.—Simple cooking must be included in this category. Many potential foods are not utilizable in their native condition. Many of these methods do not affect health, but some are of great importance. Those which demand most consideration are processes which remove part of the food and only preserve the white and finer parts. The preparation of white flour instead of wholemeal flour is by far the most important of such manipulative changes, while the polishing of rice and other cereals also comes under consideration.

3 Manipulation to Provide a New Type of Food.—Numerous foods of this class come under this heading—such as cheese, butter, beer, vinegar.

4 Food Sophistication with the Substitution of one Article either in Part or Wholly for Another.—Sometimes this is done to make a food more palatable or appear more attractive, but usually it is a fraudulent manipulation to save money by the substitution of a cheaper for a more expensive food. Well known examples are the use of potato starch for other starches, margarine for butter, adulteration of milk with water or skim milk, and undue amount of bread in sausages.

5 Accidental Contaminations.—These are liable to occur in all food manipulation, and may be chemical, bacterial, or parasitic.

Discussing the relationship of these practices to health conditions we can conveniently group them into three classes—namely, defects as regards nutritive properties, bacterial (and parasitic) infections and their consequence, and chemical contamination.

The Effect of Manipulative Changes upon the Nutritional Properties of Foods

There is probably no subject of greater interest and importance in relation to public health under discussion at the present time. The crude manipulations, such as the removal of proteins, the substitution of proteins of less nutritive value for higher, or the removal of fat, have long been recognized as detrimental and made the subject of penal enactments. It is rather in regard to finer and less quantitative alterations that chief interest arises to-day. The most important are diminution in the vitamin content and alteration of the mineral balance as regards such inorganic bodies as calcium, phosphorus, and iodine. Our knowledge of the importance of these substances is of recent origin, and in spite of much intensive research is comparatively limited.

Speaking generally, it may be accepted that food manipulation is liable to damage the vitamin content of foods so treated and may upset the physiological balance and availability of contained salts. A good many writers, however, go much further, and suggest that all food manipulation is harmful, and that a community is healthy, as regards its food supply, directly in proportion to the extent to which it is fed on foods which are in no way altered from the form in which they are delivered from Nature's laboratory. While not stated so precisely, this is very definitely the form of much modern propaganda work. Indeed, the extremists go much further, and propound the view that the physique of the people is deplorable (C 3), and that this defective and widespread condition is directly due to the fact that the nation suffers from vitamin starvation, much of which is due to the fact that our food is largely unnatural and sophisticated. Cooking is a form of manipulation comes in for sweeping condemnation, and this "babe to the raw" school would have us believe, further, that this vitamin

deficiency, which they allege to exist, is a direct incentive to overfeeding, with the added accompaniments, to make our flesh creep, of chronic intestinal stasis, decomposition in the large and small bowel, absorption of toxins and chronic poisoning, followed by rheumatism, cancer, and most of the rest of our fleshly ills. Apart, however, from such extreme conceptions, for which I fail to find a reliable basis of fact, certain considerations of the greatest practical importance do arise, some of which I propose to discuss.

In the first place, have we reliable information in regard to the extent to which food manipulation does damage the vitamin content and salt balance? It would appear that the general tendency at first has been to assume material damage, or even elimination, as the result of many processes, and that later investigation has shown that the damage has often, or even usually, been less than was anticipated. I have more particularly studied this point in connexion with canned foods. The primary assumption was that canned foods were devoid of vitamins. Later knowledge in regard to heat action, and particularly of the fact that it is oxidation rather than actual temperature which is of importance, has shown that the vitamin content may not be extensively impaired, especially as regards vitamin A. With increased knowledge it is being ascertained that it is possible to prepare canned foods with considerable, possibly unimpaired, vitamin content.

I would suggest that our knowledge is far too recent to enable positive statements to be made as to the effect of heat upon vitamin content, and that while as regards some food manipulations, such as the production of white flour, there would appear to be clear evidence of vitamin loss, for others we cannot yet speak definitely. For practical purposes we can only say generally that food manipulation is likely to be detrimental to vitamin content, and as such is potentially unsatisfactory.

In the second place, is there evidence that considerable sections of the community so feed themselves that they receive insufficient vitamins to maintain full bodily health? We are all convinced of the fact that the total deprivation of vitamins will cause specific deficiency diseases. The Vitamin involuntary experiment demonstrated that widespread lack of vitamins will cause disease. It is a plausible hypothesis to correlate deficiencies in health of our population with inadequate vitamin intake, but I have not come across any evidence which entitles us to affirm that the methods of food consumption of sections of the community are such that they ensure a deficiency of vitamins and that this deficiency is definitely related to conditions of ill health. At present it is purely an assumption.

A third consideration is whether there is any evidence associating some particular disease, or form of malnutrition of a particular section of the community, with a deficiency of vitamins or other food essentials in their diet. Here there is positive evidence, and the association of such diseases as goitre with iodine insufficiency, or rickets with vitamin deficiency (together with other factors), stands upon a strong basis of experimental and clinical evidence. On the other hand, the assumption that much malnutrition and general impairment of health in the community is due to vitamin deficiencies in the diet does not as yet seem to be supported with evidence of any cogency, whatever the future may be able to advance. Assuming that food manipulation materially damages vitamin content we have no evidence that the dietary habits in England are such that the proportion of such foods consumed is large enough to reduce to any material extent the vitamin requirements below a safety margin. It has to be remembered that the amount of vitamins required is extremely small, and it may well be true that even with a diet containing a large proportion of manipulated food the rest of the food intake may give all the vitamins required for full health.

Recently the conceptions of vitamin deficiency have been given a pathological basis. Crummer, Funder, McCarrison, and others have brought forward striking experimental evidence that deficiency of vitamins is associated with degenerative changes in the mucous membrane of the intestines and other organs, and that this is associated with a diminished resistance to bacterial infection from the small intestine. Such pathological conceptions are of great interest and importance, but are up to the present

associated with marked deficiency of vitamins in experimental work upon animals.

If these theories are true we should expect definite chemical confirmatory evidence. For example, countless children have been fed upon boiled milk without the addition of any added vitamins, and yet reliable observers have failed to find any evidence of disease from vitamin deficiency, although definite disease will result if vitamins are completely absent. Crummer remarks "The children of the poorer classes in whose dietaries bread and margarine play a large part are cut off from their main supplies of vitamins A and B." This being the case we should expect chemical and epidemiological evidence of poor physique and malnutrition and excessive infection amongst the children. School medical officers are in a particularly suitable position to provide such evidence, yet the essential facts seem to be that any evidence of malnutrition is associated rather with a diminution of adequate food, and that insufficient calories is the primary factor.

As regards ordinary food constituents, natural habits required with unrestricted food supplies have always been held as a valuable guide to what are really necessary components of a diet. Evidence seems yet to be lacking as to whether there is such a thing as a physiological craving for vitamins. If, for example, we are dealing with foods which are deficient in vitamins, do we, to satisfy this physiological craving, tend to eat excess of the deficient articles in order to obtain the necessary amounts of vitamin? It is a possible causation and explanation of overeating, and some evidence for or against such a hypothesis is very desirable.

I do not presume to say that the conceptions mentioned above as to the relationship of ill health in the community with a deficiency of vitamins in the diet are untrue—indeed they are extremely attractive, merely that they have yet to be proved as sufficiently accurate for them to be adopted and used as a basis for a public health campaign to interfere with modern dietetic habits. If we realize the need for proofs there is much more likelihood of attention being paid to their acquisition. By all means let us advocate the importance of vitamins in the diet, but not on grounds we cannot substantiate. There is a danger that the weight of public health activities may be diverted into directions in regard to which we are not yet in a position to speak with unimpeachable authority.

Bacterial Contamination

Foods in their raw state, including animal foods if from healthy animals, are for practical purposes free from bacteria. The more the food is handled the greater the opportunity for bacterial contamination and the greater the liability for it to be infected with pathogenic bacteria. While all manipulated foods are liable to bacterial infection, many of them are subjected subsequently to methods of treatment, mainly in the direction of the application of heat, which either sterilizes the product or reduces materially the number of living bacteria. Foods are so numerous and types of manipulation are so varied that it is impracticable to describe them in detail, and the danger can best be considered by discussing the general principles which are involved.

1 While bacterial additions from dust or other air-borne sources may be considerable, pathogenic bacteria are far more likely to be added from direct human handling. In manipulated foods it is usually impracticable to eliminate direct handling, but in many processes it can be greatly reduced, and in some—such as many canned food methods—there is very little direct handling. For example, in the canning of sardines in Maine (U.S.A.), as seen by me, the only stage in the complicated series of manipulations during which the small herrings are directly touched by hand is when they are picked into the tins.

2 Great importance is to be attached to the use of food which is sound initially. It is a mistake to suppose that this is a minor matter if sterilization is practised subsequently. This point is of considerable importance in connexion with canned foods. Sterilization by heat is governed by many factors, one of which is the number of bacteria which have to be destroyed. If the food is initially unsound it is liable to be heavily contaminated

with bacteria which have found conditions suitable for multiplication, and the likelihood of the survival of some of them is materially increased. For instance, *B. botulinus* is an obligate anaerobe which finds a suitable medium for multiplication on or within damaged fruit and may produce considerable toxin. Given the same degree of heat treatment, the danger of the survival of spores, or even of toxin, is increased by the use of damaged fruit or other food.

The relationship of initial numbers to survival and decomposition changes is well illustrated in some experiments of mine* upon yeasts in sweetened condensed milk. For example, in one experiment in which the yeast cells added to different tubes of condensed milk were respectively 20, 200, 2,000, 20,000, 200,000, 2,000,000 no gas production took place in the first two tubes with 20 and 200 yeast cells even after thirty-four days; gas production was greatly delayed in the tubes with 2,000 and 20,000 yeast cells but resulted within a few days in the remaining two tubes. This experiment and numerous others conclusively demonstrated that the survival of a few yeasts even of fermenting type, was inadequate to cause blowing of the tins and that this only resulted if they were sufficiently numerous to produce enough enzyme to break down the saccharose and produce gas. They were then comparatively independent of any oxygen supply and could continue to develop gas under the anaerobic conditions present in the tin.

3 It is possible to enunciate factors which will differentiate the degree of danger from bacterial infection. From this point of view we can divide manipulated foods into a number of groups, passing in order from the least to the most potentially dangerous.

(a) Bacterial contamination of a food which is a non-multiplying medium for bacteria and which is eaten only when cooked (least dangerous). Ordinary cereals such as rice or oatmeal are examples. These may be contaminated from mice excreta or other sources, but such added bacteria do not multiply if the food is kept dry and quickly die out, while subsequent cooking is a further powerful safeguard.

(b) A food which is a non-multiplying medium but which is not subsequently cooked. Bread is perhaps the best example. Much has been said about the dangers of infection from unwrapped bread, but in view of the absence of a multiplication factor I am not prepared to rate the dangers of infection as having an importance as great as those concerned with made-up meats and other similar foods.

(c) A food which is a multiplying medium for bacteria but which is not subject to slow cooling and which is subsequently cooked. The degree of the cooking and the nature of the food are important factors. Ordinary meat sausages are a good example. Bacteria will multiply greatly in such a food, but not at the same rate as in foods cooling slowly. Sausages will often contain very numerous living bacilli, and as they are frequently only lightly cooked a good many may survive. Even non-sporing pathogenic bacilli, such as those of the food-poisoning group, will survive in lightly cooled sausages. With some of the German types of sausages—such as blood or blood pudding sausages—in which the primary material is more liable to contain pathogenic organisms, the need for thorough cooking is still more obvious.

(d) A food which is a suitable multiplying medium for bacteria which is heated in preparation, but which is subsequently cooled slowly and eaten without further cooking. Ordinary brown is a typical example. Bacteria readily multiply in it. In preparation the cooking should destroy any bacteria present, although this is not always the case in practice, but it is then put to cool and cools very slowly. If a food-poisoning bacillus gains access the temperature conditions favour rapid multiplication, and since the food is not further heated they are consumed alive. Many outbreaks of food poisoning have originated from foods of this class, including brown, potted meats, and meat pies.

(e) Most dangerous of all are foods exactly similar to (d) but for which the materials used are in their native state liable to contain bacteria, and possibly pathogenic bacteria. Made-up foods containing viscera are foods in question, and since pathogenic bacilli are more likely to be present in liver lungs, intestines, etc., their preparation requires special care. Fortunately these types of food are not in great favour in this country.

I believe it is of real importance and value to compile some such scale so as to be able to assess the relative danger to health of any type of manipulated food and to prescribe the precautions necessary to remove or minimize such risks. It is absurd to group all foods together as if the dangers were the same. Unfortunately these considerations have not been followed by our Legislators, and we have, for example, plenty of legal enactments dealing with bake houses, but none giving control over premises which prepare made-up foods, such as meat pies, brown, potted meats, and the like. For many years I have been pointing out the need for such special supervision and control. In a report on food poisoning³ issued last May we point out—

"Such special supervision could best be exercised by requiring that every person carrying on such a business should be licensed to do so by the local authority. Before granting a licence the local authority should be satisfied that the premises were suitable, that the procedures were likely to be conducted in a clean manner, that they were not carried out in proximity to undesirable trades, and that the measures for protecting the foods when made, and especially during the cooling stages, were such as reasonably to prevent bacterial contamination."

The subject is of special importance in relation to food poisoning outbreaks, and the following figures as to the vehicle of infection in 203 such outbreaks will be of interest. These all refer to outbreaks in the British Isles, and many of them were personally investigated and bacteriologically studied by Mr. Bruce White and myself.

	Number	Percentage
Canned meat	31	
Canned marine products	27	30.5
Canned fruit	4	
Milk	14	6.9
Milk products	16	7.9
Made up meat	54	26.6
Manipulated meat	10	4.9
Fresh meat	33	16.3
Fruit and vegetables (not canned)	8	3.9
Other foods	6	2.9

This table shows what a large part foods which have been made up and manipulated play in food poisoning. They constituted 72 per cent of the whole, apart from some of the fresh meat cases in which some manipulation took place.

4 No finality has been reached under practical conditions of preparation in obtaining a satisfactory formula, which is always applicable, between the degree and amount of heat required on the one hand and freedom from pathogenic bacteria on the other. Two types of food may be mentioned in illustration.

In the manufacture of canned foods in order to obtain sterilization it is not the simple matter of the application of a known degree of heat for a definite time but all kinds of factors operate which profoundly affect practical conditions. Some of these factors such as the physical properties of the food and the degree of acidity vary with each type of food canned and sometimes with the same food. For instance the percentage of starch affects the formation of convection currents and thus delays heat penetration. To quote from Bigelow's excellent monograph in a series of experiments with 2 per cent of starch the centre of the can reached retort temperature of 250° F. in about fifteen minutes but with 3 per cent of starch it took about eighty minutes in creasing to 120 minutes with 5 and 6 per cent of starch. With the low percentage of starch the heat transference is due to convection currents, with the higher almost entirely to conductivity and so lags greatly. The ascertaining of suitable lethal temperatures for the bacteria in canned foods is therefore a matter involving numerous scientific considerations. In practice many perfectly sound canned foods are not sterile and my results for a long series of sound sheep samples gave 38 per cent not sterile, excluding sweetened condensed milk, which is never sterile.

The pasteurization of milk may be mentioned as another example since it may be regarded as a manipulated food. There is still considerable lack of uniformity of opinion as to the exact temperature and period of operation to secure destruction of pathogenic bacteria in heated milk without damaging it.

5 The risk of contamination from human sources in the later stages of preparation and in distribution is an important one, and there is evidence of disaster being so

spread. The importance of eliminating this kind of contamination is obvious and will be discussed in more detail by Dr Goddard.

Chemical Contaminations

These are of two kinds: substances introduced unintentionally, and those added deliberately. Unintentional chemical additions may be of many kinds, but are mainly either introduced from processes of manufacture—such as arsenic in beer or sweets, lead in cider and other foods—or added from the action of the food upon the container, tin in canned fruits being the best known example. Deliberate additions include the addition of chemical substances to preserve foods from decomposition, additions to enhance the appearance of foods, such as copper salts to vegetables and peas, or the addition of colouring matters and the use of such chemical mixtures as flour improvers, which in part are fraudulent in intent.

The subject of chemical preservatives in food is a form of food manipulation of great practical importance. My own views are clearly set out in the following quotation from one of my books¹ (1919).

'The new Ministry of Health with its advisory bodies of experts should find it perfectly feasible to enact suitable regulations setting out the preservatives which may be used with the maximum amounts for the different foods requiring that if these permitted substances are added the fact must be adequately set out on the label and prohibiting the sale of preservatives under fancy names. The addition of all preservatives outside this permitted schedule should be completely prohibited. It is quite useless to say that certain specified preservatives should be prohibited and leave the matter there since the trade chemist can always be relied upon to find fresh ones. The attitude to be adopted is that of prohibiting all preservatives except those scheduled as permitted under defined conditions.'

This is exactly the basis of the recommendations of the Committee on Preservatives and as embodied in the draft regulations of the Ministry of Health.

I do not propose to discuss these chemical contaminations and their prevention, as this aspect of the subject will be dealt with by a subsequent speaker.

In opening this discussion it seemed to me that it would be most helpful if I attempted to cover the ground on broad lines, only filling in certain sections, either because I had data from my own experience to offer which served to elucidate the subject, or because certain aspects appeared to me to be of special importance. I have no doubt that other speakers will wish to emphasize other sections and will complete the review of this very important subject.

ACCIDENTAL CONTAMINATION OF FOOD

What is so admirable about the address we have just heard is that every statement made therein is founded on a scientific basis. Dr Savage is one of those who could not offer any suggestion unless he had proved it from his great experience. I cannot claim that kind of experience nor his opportunities of research, but I feel, and feel strongly, and I am sure you do, that there is a good deal to be said, and a great deal more to be done still on the practical side of the question of the accidental contamination of food, and generally on food pollution. I shall therefore, in the few moments that are mine, place before you a few points worthy, I hope, of your consideration and support.

It may be taken for granted that in its preparation, in its storage, exhibition, and distribution, food is seriously polluted, mainly from lack of ordinary precautions, and we all know that every kind of bacterium has been found on and in the food put before the public. Now, I do not wish to infer that these bacteria are always placed on culture media that are ideal for their growth, or even for their existence, nor that they are responsible for a large amount of infection and disease, but I do insist that so long as there are so many lacunae in our knowledge of the origin of so many diseases, so long as so many of the sources of food poisonings are so obscure, it is incumbent upon us to eliminate as many as possible of the more obvious and grosser pollutions, at the same time pointing out better methods and suggesting remedies as they occur.

As a typical instance of gross contamination, let me remind you of the account given recently in a well known daily paper of the inspections made by a member of Parliament at Smyrna of the methods used there in the storage and packing of figs and sultanas. In that account he gave most disgusting details. Still more recently another paper, by way of explanation, if not of defence of Smyrna, published an article excusing the use of bare feet, and finished with the following note: "No doubt in some of the smaller houses evasions of the sanitary regulations may take place, but not in those competing for the American market." It went on to say, "If the British public are anxious as to the purity of their sultanas, the remedy would seem to be to adopt the American methods of consular supervision." I think you want no clearer admission of default than this paragraph. So it comes to this, that for long years past we have all been obliged to consume large quantities of filth, with results we can hardly gauge, as we are still ignorant how far this contamination of dried fruit is sterile or potent for evil on arriving in this country. In any case, we ought not to be asked to eat Oriental filth. With regard to this matter I think the obvious reply should be that our own colonies should lose no time in placing on the British market in every town these and other dried fruits in cartons, not necessarily to compete with the smaller tradesmen, but to create a demand and to educate the public to purchase only food for which a guarantee can be obtained that it has been prepared, stored, packed, and distributed in a cleanly manner. I feel that something should be done, and soon, to clean the atmosphere and satisfy us with better methods. Coming nearer home, I think the same argument applies to bread, you can all note four, five, or six separate contaminations from the oven to the home. Heaven knows how many occur in the house, often more than four before the bread is eaten. Here the remedy is at hand, has been tried, and has been found efficient—namely, to wrap bread, cakes, and similar food in waxed paper, and this paper should not be removed till the bread is consumed on the table. A bacteriologist tells me he has isolated streptococci and all forms of bacteria on the surface of bread. When we remember that more than 80 per cent of tuberculosis is in middle life derived from human and not bovine sources, and that a large proportion of those notified to us as health officers are never traced, when we think, for instance, of a dozen different people handling the bread on the sideboard to help themselves, we cannot be surprised at the wide dissemination of bacteria when the propagation is so easy. Every medical practitioner attends cases of sporadic infectious disease, and sees acute cases of gastrointestinal irritation in his practice for which neither he nor his patient can account. Fortunately, the majority of us are immune, and can deal physiologically with almost every form of bacterium except the members of the Gartner group, but one never knows the moment when that immunity ceases, and at any rate, we have a very clear and definite duty to protect others.

The unnecessary handling of food is almost universally practised, and is really most reprehensible. Go to the fruiterer's and watch women, even of good class pinching the greengroceries or the buns at a confectioner's. This kind of wilful pollution will continue till sanitary officers have more power to deal with this danger by suitable regulations from the Ministry of Health. Why should greengrocers be

permitted to expose their edible foods, as now obtains? We really want similar powers with limiters that we have with meat and milk. Go to the back streets of any town, and see the small grocers' shop fronts piled up with sugar, dried fruit, biscuits, chocolates, etc., and covered with flies and bluebottles by day and with cockroaches by night. Such exposure is not so much accidental contamination as premeditated pollution, and should certainly be prevented. Why should poorer people have polluted food? We have, as health officers, a good deal of power in a borough, but practically none at all in the shop, even now one often sees the assistant dribble the sweets from the hand into the scale pan until the exact weight is obtained. It is up to the public to condemn these faulty methods at once, and in strong terms. It is up to the press to instruct in better methods. You may say what you like about newspaper medical references, but with all our teaching, our societies, and lectures we have nothing like the power of the press—only the press should take care to be well informed first.

We have at last I am glad to say, the new Meat Regulations, giving better control of meat of slaughtering, and the slaughterhouse, but what is essential now—and we all heartily support Dr. Savage in his contention—is that all premises where made up meat foods are prepared for public use should be licensed so that frequent and thorough inspections can be made of those premises, of the ingredients used, and of the methods employed. Of course we can now inspect wherever food for the public is prepared—if we know—but we require the licence for systematic inspection. The same applies to ice cream vendors, though I am aware that many large authorities and counties have their own by-laws and regulations with regard to this.

The new Meat Regulations though welcome as a first instalment and no doubt good in parts, are wholly inadequate for present needs. With regard to milk, the public is duly obtaining a purer supply, and there is less adulteration and contamination. Every effort is being made by the county medical officers and the large distributors to induce farmers and draymen to deliver milk of high standard, and, we may say, on the whole successfully, but alas! it takes one almost weep to think how this valuable food is treated in the home. How very few people think it worth while to sterilize their jugs and utensils or protect the milk from flies and vermin! We all know that with the greatest care and vigilance in these rushing times it would be impossible to eliminate all sources of contamination of food, but nothing can excuse the appalling ignorance and want of care so often displayed in the treatment of food in the kitchen. There must be something very defective in the training of the home and in the schools that produces such a mass of incompetent, wasteful people who are responsible for the preparation of the food of the family, where so much pollution occurs, and so much damage to the vitamin content.

In paying tribute to the opener of this discussion for his learned and comprehensive address, I should like to thank him for allowing me to place before you these few points on the subject of the accidental contamination of food.

GENERAL DISCUSSION

Dr. J. BROWN (late M.O.H. Bury) said he had found one of the most frequently contaminated articles of diet to be cooled porridge, which was often retrieved as such from small shops in industrial districts.

Dr. CUNNINGHAM (London) thought there should be more supervision over cold storage, which he believed was responsible for some deterioration of food values.

Dr. H. SCURFIELD (late M.O.H. Sheffield) agreed with Dr. Savage that there was a tendency in certain quarters to make extreme and exaggerated statements on this matter. Even those engaged in the vitamin research work were liable to make loose generalizations. For example he had read pronouncements to the effect that the deterioration of milk destroyed the vitamins, whereas the truth appeared to be that only one vitamin, and that

the only reduced vitamin C, was affected by this process. He would like to see more exact work done with regard to the vitamin content of such common foodstuffs as jam and marmalade. He believed, however, that there was evidence sufficient to connect the universal prevalence of dental decay, constipation, and the poor physique revealed by recruiting statistics with vitamin deficiency, and thought we were on safe ground in advocating the increased consumption of milk and dairy products, more fruit and more green vegetables. Above all people ought to learn to adopt a diet which secured freedom from constipation.

Dr. S. NOX SCOTT (Plymouth) thought there was some ground for forming a general attitude of bacteriophobia, and although a little of that disease might be good for us, anything like an epidemic of it would be deplorable. With regard to milk they had neglected, though fear of vitamin deficiency, to advise the public to take two most simple precautions—namely, to cook all milk and add to the diet more fresh food and vegetables. It was always found that the mere mention of further regulations with regard to imported foods was immediately made the ground of political "stunts" and agitation by vested interest, a recent example of this was the outcry that had been made about the importation of foreign eggs. One of the most curious aspects of the food question centred round the impunity with which putrid food, especially game and cheese, was consumed by some people, and particularly that section of the community which was so ready to take advice to the rest of the nation.

Professor F. I. WATTS (M.O.H. Sheffield) regretted that so many medical men seemed to be unaware that it was their duty to report cases of suspected food poisoning. In several instances cases had only come to his knowledge on seeing a report, frequently exaggerated, in the lay press. By that time, of course, it was too late to obtain samples of the suspected food or clinical material from the patients, and thus valuable opportunities for investigation were lost. An extreme instance of manipulation of food was found in certain popular and much advertised proprietary articles. Some of these might contain some nutritional value, but even so it was obtained at an exorbitant cost which was deplorable in these days of general poverty. He considered it most unfortunate that many of these articles were "pushed" by the staffs of nearly all child welfare clinics. The mothers should be taught to get value for their money from natural fresh foods and cod liver oil.

The Chairman, Dr. LUSTIG HILL (County Medical Officer, Durham), agreed that it was important to avoid the suspicion of "stunts," which were always marring their appearance in connexion with medical matter, especially public health. Nevertheless, he was in agreement with the principles of the draft regulations as to preservatives, as was the Public Health Committee of the Association. Although he thought the risk of any dangerous contamination of bread was very small, he thought the wrapping of loaves was nevertheless a valuable procedure, merely as a hygienic example. That was an aspect of the question that should not be lost sight of, for such examples were the best means of educating the public to a higher standard of really hygienic cleanliness, and thus indirectly bringing about an improvement in the health of the community.

Dr. SAVAGE, in replying to the points raised in discussion, said that there was no reason to suppose that putrid meat was unwholesome. It was seldom eaten because it was generally unpalatable, but the old idea that food poisoning was caused by chemical substances produced in the process of saprophytic putrefaction was based on a complete misapprehension of facts. The term "ptomaine poisoning" had long since been dropped out of scientific vocabulary, and he had hoped that the theory on which it was based had been forgotten.

MEDICAL, SURGICAL, OBSTETRICAL.

DEATH FOLLOWING THE PASSING OF THE STOMACH TUBE

THE passing of the stomach tube is such a common and simple proceeding, and accidents are so rare, that it seems advisable to put this case on record because of the untoward result which followed this method of investigation.

J O, a foreigner, aged 50, was sent to see me in April last complaining of pains in the epigastrium and behind the shoulder coming on soon after the taking of food and accompanied by flatulence, in addition to much shortness of breath on exertion. He complained also of weakness and loss of weight. The pain was first experienced after dinner on December 8th, 1924, but since then had become very constant, and was aggravated either by food or on exertion. It was not sufficiently severe to make him stop if he were walking. He was a stoutly built man, and said that he had always been healthy till the onset of the present symptoms.

I found that the heart dullness was not definitely increased, the apex beat was not palpable, the sounds were pure, and extra systoles were present every seventh or eighth beat. The blood pressure was 140/90 mm Hg. There was no evidence of neuritis. There was no tenderness in the abdomen, the stomach was not dilated, the liver was not enlarged, the urine contained no albumin, the fundi were normal. The patient had previously been x-rayed, and nothing abnormal was found in either stomach or bowel. His tongue was coated with white fur, and a powder containing belladonna, ipecacuanha, bismuth subchloride, and sodium bicarbonate was prescribed.

In a month's time the condition was if anything, worse. The patient had a burning feeling behind the sternum, and pain in the epigastrium and behind the shoulders, and the shortness of breath was more troublesome while the loss of flesh had become more marked. Meritine the Wassermann reaction had been found negative. He was admitted to the Western Infirmary in the middle of July. His blood pressure then had fallen to 107/90. A soft systolic murmur had developed at the apex. He was given an Ewald's test meal and 40 ccm of filtrate was removed, with a total acidity of 18 but no free hydrochloric acid. There was no occult blood in the stools. A further x-ray examination was made of the stomach, and no abnormality was detected except that in one of the films there was some spasmodic narrowing at the pylorus. While in bed he complained of no symptoms. Three weeks later a further test meal was given to determine whether there was any alteration in the gastric acidity. When the tube was passed to remove the contents the patient had an attack of coughing and a drachm or two of fluid was ejected from the tube. He suddenly became very pallid and the tube was immediately withdrawn, but he died almost instantaneously. There was no external bleeding. The only explanation that could be offered was that the patient had had an attack of syncope or angina set up reflexly by the passing of the tube. *Post mortem* examination was not permitted. On the previous occasion on which the test meal had been given the patient had also had some coughing, but otherwise was not specially disturbed.

FULL-TIME PREGNANCY IN A BICORNUATE UTERUS

UNTIL I saw the case reported in the BRITISH MEDICAL JOURNAL of August 8th (p 256) by Dr Moyes I was not aware that this condition is regarded as rare. I have in my records the following case, where not one but a series of full-time confinements took place in a patient with a double uterus, the presence of the condition being discovered in rather a curious way. The first normal confinement was in August, 1918, the woman then being a primigravida about 25 years of age. I have no note of anything unusual at that time. Between then and her next confinement in January, 1920, she had an attack of pyelitis. In the second confinement the presentation was a breech, but otherwise not abnormal, and also full-time. She had further kidney trouble in that year and unfortunately again became pregnant in July, 1920. Her general condition was very poor, and in consultation with another practitioner, I decided that she ought not to go on with this pregnancy, and procured abortion at the third month,

after having emptied the uterus I was inserting the nozzle of the uterine douche, when I found that apparently it would only enter some two inches, whereas, of course, the blunt curette had entered perhaps four. Examination revealed a septum in the upper part of the cervix, dividing the entry of the right side of the uterus, which had been pregnant, from that of the left, which had not.

This patient was confined again in 1924, and although I took particular care to see if there was anything to indicate the abnormality either in pregnancy or at confinement I was not able to feel the non-pregnant horn of the uterus or to discover any sign of it by vaginal examination during labour. I did not think it justifiable to make an intrauterine examination after the birth for this purpose.

I think there is no doubt that in this case, unlike that of Dr Moyes, the non-pregnant horn of the uterus did not enlarge along with the pregnant one.

One curious feature remains to be mentioned. The patient suffered from a certain amount of menorrhagia at times, and it was noteworthy that this occurred principally at alternate periods. My suggestion is that this depended upon which Fallopian tube the ovum had entered, one side of the uterus being apparently more fully developed than the other, and not partaking of the menstrual disturbance when the other side was affected.

OPTIC NEURITIS DUE TO DISEASE OF THE ANTERIOR ETHMOIDAL CELLS

DR J A GIBB, in the JOURNAL of July 4th (p 12), states that as far as he is aware there are no recorded cases of optic neuritis and retrobulbar neuritis due to disease of the anterior ethmoidal cells. The following case, therefore, seems worthy of mention.

On June 18th 1923 a lady of 50 complained of pain in the right eye of nine days duration that the eye was slightly tender to touch and that the sight in that eye was becoming clouded. Her vision was right eye 6/36 and left eye 6/6. The ophthalmoscopic appearances were those of neuritis of the acute retrobulbar type. Dr McNabb confirmed the diagnosis suspected nasal sinus trouble as the cause and referred her to Mr Lindley Sewell.

A week later Mr Sewell removed the anterior end of the middle turbinate and found this cystic with one large cell filled with mucus. There was another cell external to this structure filled with mucus. The next cell opened was clear. She had limited disease of the anterior ethmoidal group of cells the second cell opened being within the ethmoidal labyrinth proper. Within a week the vision began to improve, no further nasal treatment was necessary, and on September 19th the vision was 6/9 (two letters).

HAROLD NUTTALL, M.D.

RECURRENT HAIR-BALL OF STOMACH

THE following case is, I think, of sufficient interest to merit publication.

In 1911 an unmarried woman aged 35 was operated upon at St Mary's Hospital London for the removal of a hair ball from her stomach. In April 1922 she was operated upon by Mr Washbourn of Gloucester for a similar condition and again in June 1922. When I saw her in October, 1923 she complained of pain and a swelling in her abdomen and loss of appetite of three months duration. On examination a large solid tumour was visible and palpable in the upper part of the abdomen and in view of her past medical history another hair ball was suspected. Upon opening the stomach which was much enlarged it was found to be entirely occupied by a mass of hair. This extended through the pylorus into the duodenum and when removed was found to weigh 2½ lb. it was 20 inches long and its girth at the largest circumference in the stomach portion was 15 inches. Recovery was uneventful and the patient after giving a solemn undertaking to refrain from the habit of hair eating, was discharged as cured. In November 1924 she once more complained of a return of her former troubles and I again removed a large hair ball. Up to the present I think she remains quite well.

Apart from her hair eating habits, this woman is quite normal mentally, being well educated and a very fine musician. She seems to have suffered no permanent ill effects from her repeated operations, since her abdominal wall is firm, and when her stomach is not full of hair her digestion is unimpaired.

SPLenic ANAEMIA SPLENECTOMY RECOVERY

MEMORANDA

[THE BRITISH
MEDICAL JOURNAL]

THE severity of the haemorrhages, the large amount of ascitic fluid, and the rapid recovery after splenectomy seem to make the following case worthy of record

A girl aged 5½ had weighed 10½ lb at birth, but gradually lost ground and a doctor who was consulted when she was 1 year old noticed an abnormal swelling in the left side of the abdomen. She improved a little until the age of 3 when she had a sudden profuse haematemesis. During the next two and a half years the child was constantly under medical attention and as yet no attacks of melena and six of haematemesis nearly all being severe enough to blanch the child and keep her almost constantly in bed. I saw her first in October 1924 after a haemorrhage she was desperately ill and thin. The splenic swelling was visible and palpable, filling almost the whole of the left hypochondrium. The blood was examined at the Southland Hospital Laboratory. The findings were: red cells 3 150 000 per cubic millimetre, white cells 3 200 per cubic millimetre, polymorphonuclears 49 per cent, lymphocytes 40 per cent, large mononuclears 9 per cent. The findings were: and was subsequently tapped eleven times at weekly intervals, four to seven pints of clear straw coloured fluid being removed on each occasion. Her weight before operation was 2 st. Her father's blood was tested and found to be suitable for transfusion but this was not attempted before the operation as the child was very nervous.

Operation.—On January 28th 1925 ether being administered by Dr C. Huntly Gordon I made a left supraumbilical parietal incision and ascitic fluid escaped freely. Except for a few omental adhesions the spleen was found to be free. It was swung forwards fully but during the manoeuvre the child almost collapsed. A long heavy mesenteric clump was shipped over the pedicle which we divided and the abdomen rapidly closed in layers which weighed 1 lb. Transfusion was rendered impossible by the accidental breaking during sterilization of all the available syringes. The child drank freely after returning to the ward did not vomit and made steady progress. Clear fluid escaped from the wound for some days. The clump was loosened gradually from the wound for seventy-two hours after the operation and was easily removed. There was no bleeding after the operation and the child was still weak and thin. She was tipped twice subsequently with great relief.

Progress.—Five months after the operation the mother reports that the child is well, she is much stronger, has gained 14 lb in weight does not need to be wheeled about and is much improved in general health. There has been no further ascites or haematemesis. The blood report is: red cells 4 400 000 per cubic millimetre, white cells 13 800 per cubic millimetre, polymorphonuclears 63 per cent, lymphocytes 36 per cent, haemoglobin 65 per cent.

TRANSIENT GLYCOSURIA FOLLOWING SCORPION STING

This note published in the BRITISH MEDICAL JOURNAL (August 15th, p. 294) by Dr H. E. King Fretz on transient glycosuria following scorpion sting is of considerable interest. My experience is limited to the following case. I only learnt the patient's history on his return to England.

A healthy man aged 29 travelling in the Far East was quite well until he was in Java. There about February 15th 1925 he was bitten on the leg by what he called a large spider. Swelling about two inches in diameter developed and persisted for about seven days. He began to feel limp and a definite oedema together with red blotches appeared on the legs. Down to this time the bites of mosquitoes had not troubled him but afterwards they caused a definite swelling.

While in Hong Kong he was examined and glycosuria was discovered. The blood sugar was said to be positive and the diagnosis of diabetes mellitus was made. It does not appear that he had any thirst or polyuria at any time. A fairly strict diet was ordered but the glycosuria apparently persisted since the diet was confirmed in Shanghai and a very bad prognosis given. On his journey home the strict diet was continued, and his weight began to improve as soon as the weather became cooler. When I saw him on June 22nd he still felt weak and could not walk far. He weighed about 9 lb less than his usual weight. The urine did not contain any sugar. A sugar tolerance test with 50 grams of sugar gave a quite normal result since the initial value was 0.115 per cent and the highest point reached was 0.14 per cent after thirty minutes after two hours the blood sugar had fallen to 0.075 per cent. No sugar was excreted in the urine in either hour.

I had not heard of a transient glycosuria following the bite of a 'spider' but seeing that the illness had followed the bite so promptly and that the patient's reaction to the mosquito bites had altered, I suspected that this accident had been responsible for the glycosuria. Since I saw him he

has eaten an ordinary diet. Dr H. A. Rippmer tells me that the patient is feeling much better and that the urine is sugar-free. It would be of great interest if workers in tropical countries would extend Dr King Fretz's observations and estimate the sugar tolerance of these patients. It is important to know whether the glycosuria is due to a definite hyperglycaemia or to a lowering of the threshold of the kidney so that the sugar escapes into the urine although the blood sugar is normal.

DLATH FROM HAI MORRHAGE IN SCARLET FEVER

Arthritic haemorrhage resulting from erosion of some of the large vessels in the neck, as is possible cause of death in scarlet fever and its complications, is mentioned in some textbooks, such cases are sufficiently rare to warrant publication of this one.

I was called recently to see a girl aged 7 suffering from sore throat, headache, fever and general malaise. I made a provisional diagnosis of scarlet fever and the next day the appearance of the rash, red tongue etc., confirmed the diagnosis. All went well for about ten days after which there was swelling of the left superficial cervical glands at the angle of the jaw. I decided to open the mass but this was refused by the mother who preferred that it should 'break'. On the twentieth day of the disease the mass broke and large quantities of pus (about half a pint according to the mother) discharged. A great deal of sloughing followed so that after a few days the external jugular vein and the external carotid could be seen over the sloughed area. All went well for about a week when the glands on the opposite side became swollen and aphthae developed. Under treatment the recently swollen glands began to recede to their normal size while the edges of the left side (sloughed) began to show signs of healing.

I was just beginning to think that after all the case would terminate favourably when on the thirty-fourth day of the disease with no warning or any intimation—for example changing dress, picking by the child or undue exertion—the external jugular ruptured and the child died of haemorrhage before I could be reached or any medical aid could be obtained.

A. CALDER, M.D., C.M.

ACUTE APPENDICITIS ASSOCIATED WITH SARCOMA OF THE APPENDIX AND VOLVULUS OF THE CAECUM

The following case is of interest owing to the variety of conditions present.

A boy aged 15 was admitted to Addenbrooke's Hospital with a diagnosis of acute appendicitis. The bowels had not acted for four days and the pulse and temperature were both slightly raised. There was a well marked lump in the right iliac fossa and the abdomen was tender and moderately rigid.

Operation. (Brittle's incision) revealed tonsils, a large omental mass the size of the palm of the hand enclosing the appendix and an abscess cavity which had burst into the caecum. The omental mass was attached to the transverse colon and the caecum was rotated on its mesentery. The terminal coil of the ileum entering its right side. The appendix was removed from the transverse colon and after some difficulty the omental mass was freed and the abdomen closed with a drainage tube. After removal of the appendix was dissected from its omental sheath when it was found to be continuous with an abscess cavity just distal to which was a hard lump the size of a pigeon's egg of apparently fibrous tissue the real cause of attachment to the transverse colon. On microscopic investigation, however, this lump was found to be a spindle-celled sarcoma presumably of the tip of the appendix.

Before and after operation the urine contained sugar but it disappeared after ten days. The patient was discharged after seventeen days in hospital.

The interesting points in this case are the large number of different conditions present—appendicitis, peritonitis, volvulus, sarcoma, and glycosuria—and the fact that the acute appendicitis drew attention to an early sarcoma which I am indebted to Mr W. H. Bowen, honorary assistant surgeon to Addenbrooke's Hospital, for permission to operate on and publish this case.

Reviews.

TUMOURS OF THE SPINAL CORD

THE newly published monograph on *Tumors of the Spinal Cord and the Symptoms of Irritation and Compression of the Spinal Cord and Nerve Roots* by Professor CHARLES A. ELSBERG of New York is an important contribution to neurological and surgical literature. It embodies the results of his remarkable experience during twelve years of one hundred verified tumours of the cord and its membranes, all of which he observed and operated upon himself. In 81 of these the tumours were submitted to histological examination, thus giving a completeness to the records which in this subject is unrivalled.

More than half the book is occupied by the detailed histories of these 81 cases, but the author has done wisely to print these individual records. Far from its being a weariness to read the case reports, they will be found deeply interesting and instructive. The predominant clinical features of each case are recorded fully but concisely, and each is accompanied by charts of the sensory changes. In nearly all excellent illustrations are provided of the condition found at operation, and of the naked eye and microscopical appearances of the individual tumours. The report of each case is followed by comments on the lessons to be learned from it, which illustrate the gradual growth of the author's experience.

The second half of the book contains a systematic study of the subject. Classifying the tumours first in reference to their relation to the cord, it appears that three-fourths were extramedullary, and that of these 78 per cent were intradural and 22 per cent extradural. The tumours are classified also according to their relation to the anterior and posterior nerve roots and the dentate ligaments. The occurrence in a small number of cases of a "reversed Brown-Sequard syndrome" is noted. This Professor Elsberg believes was due to the pressure of the bony spine on the side of the cord opposite to the lesion. His experience is opposed to the common belief that pain is always an early symptom. In 27 of the 81 cases there was no pain at the onset, in only 8 cases, however, was pain absent throughout the illness. He lays stress further on the occurrence of paresthesia or abnormal sensations short of actual pain, and divides the clinical features into a first stage, in which the symptoms are usually irritative, and a second stage, in which symptoms of interference with cord functions become manifest.

The diagnosis of tumours at different levels of the cord is considered in detail in successive chapters, and the differentiation of tumours from tuberculous or malignant disease of the spine, and from intraspinal diseases such as multiple sclerosis and syringomyelia. An erroneous diagnosis of Pott's disease is in his experience more frequent than the diagnosis of cord tumour in a patient with tuberculous bone disease. There is a chapter on the examination of the cerebrospinal fluid in cases of tumour. In 39 per cent of 77 cases xanthochromia was present, it was most frequent in tumours of the lower thoracic and lumbosacral cord, and was almost constant in large tumours of the conus and cauda equina. Excess of protein with a normal number of cells was common but not constant. He has not made use of the method of Sicard of injections of lipiodol into the cisterna magna.

The operative mortality was 10 per cent, but for the extradural tumours it was only 5 per cent. He concludes that the majority of patients with cord symptoms due to an extramedullary tumour of less than two years' duration will recover after removal of the growth and be able to resume their former occupation. This is a very impressive fact and is in general accordance with the experience of other workers. It should convince the practitioner of the heavy responsibility which rests on him to bear in mind the possibility of an operable tumour being present in any case suggestive of a local lesion of the spinal cord. There can be no doubt that a good many of these patients are allowed

to go on to a hopeless condition of paralysis under the diagnosis of "myelitis," who might have been cured or greatly relieved by early operation.

The price of the book is high, but the illustrations are numerous and the general production excellent. There are odd printing mistakes and some errors in the bibliography—for example, reference 136 should be "Walshe" and not "Holmes and Walshe," and the Society of Neurology of Paris should not be called the French Association of Neurology.

TEXTBOOKS OF PATHOLOGY

THE third edition of BEATTIE and DICKSON's *Pathology* is now published in one volume. Apart from this and an increase in illustrations little change appears to have been made on the previous edition issued four years ago. This textbook has always been a favourite with students, several generations of whom have appreciated its concise descriptions, generous illustrations, and helpful system of emphasis with different type. The one-volume edition is likely to be preferred, not only because it means a saving of eight shillings, but also because it avoids the necessity of studying two volumes simultaneously. No one can read special pathology without having to refer occasionally to general pathology. If the province of pathology continues to increase, compelling yet bulkier textbooks, we suggest that a temporary postponement of the revision to the two-volume plan might be secured by printing on thinner paper. The present volume is only just not too thick to be grasped by the hand, but it is inconveniently heavy.

Professor WILLIAM BOYD's textbook *Surgical Pathology*³ is as its title suggests, a presentation of those aspects of pathology of most interest to the surgeon. Osler's aphorism "As is our pathology so is our practice" applies with equal truth to surgery as to pure medicine. But just as there are certain anatomical regions of much greater importance to the surgeon than others, so there are regions in pathology which have a special claim on the surgeon's attention. Books on surgical anatomy and surgical pathology are valuable because they separate out and give particular emphasis to the facts and doctrines of greatest urgency from the surgeon's point of view. Whether or not Dr Boyd's volume will achieve its object is difficult to foretell. It is accurate, clear, and well illustrated, but it seems to follow the conventional plan rather closely, being divided into two parts, the first on general and the second on special pathology. An unusual but commendable feature for a book on pathology is the summary of symptoms which accompanies many descriptions, thus providing a link between the laboratory and clinical sides. A list of useful references follows each chapter. The book is well described by Dr W. J. Mayo in the foreword as "a sincere attempt to place pathology before the student and practitioner from the practical standpoint."

OEDEMA

DR J. LE CALVE's large volume on oedema⁴ is divided into two books, and each of these into four parts. The first book gives a general and tolerably superficial account of the experimental side of the questions to which the study of oedema gives rise. The author reviews the many theories as to the causation of oedema that have been put forward from time to time—the five chief being the mechanical, the nervous, the physical and physico-chemical, the toxic, and the vascular—and finds some truth in all of them. It is the vascular or vasomotor theory of oedema that he develops most fully. He sums up oedema as a defensive reaction of the organism against an excess of water and dissolved substances which the excretories have not succeeded in

³ *Oedema* By J. Le Calve. Paris: Masson et Cie. 1925. (Med. 8vo pp. vii + 648. Fr. 30.)

⁴ *Tumors of the Spinal Cord and the Symptoms of Irritation and Compression of the Spinal Cord and Nerve Roots* By Charles A. Elsberg M.D. London: H. K. Lewis and Co., Ltd. 1925. (Sup. roy. 8vo pp. viii + 421. 354 figures. £2.10. net.)

eliminating, in addition to this physiological function, oedema has also an antitoxic function. The second book, occupying two thirds of the volume, gives a clinical account of the various pathological conditions in which oedema is observed, with a discussion of its pathogenesis of the oedema in each instance, and suggestions for its treatment in many of them. No mention seems to be made of oedema due to asplenia in the rare cases of idiosyncrasy to that drug, and in the last chapter of the volume, dealing with infantile oedemas, no reference is made to the oedema that is common in children who are rickety but otherwise apparently in good health.

Regarded as a whole, Dr Le Calvé's book may be described as the work of a clinician rather than of an experimental pathologist or physiologist; it is not well documented and contributes little more than a popular summary to our knowledge of the subject with which it deals.

CHIMPANZES AND A FACULTY OF REASONING

DURING 1914 and 1916 Dr KOHLER, professor of philosophy in the University of Berlin, studied the behaviour of chimpanzees in confinement at the Anthropoid Station in Jena, belonging to the Prussian Academy of Science. His results were published first in German in 1917. A version in English¹ has recently been issued, and in it the author has made some changes in the critical and explanatory sections, and has added some general considerations on the psychology of the chimpanzees.

The observations relate to tasks set to chimpanzees to test their possession of a faculty of reasoning. These tasks were varied in different ways, the results were influenced by the disposition of the animal, its state of health, and by the surroundings. Professor Kohler's general conclusion is that chimpanzees in confinement are suitable subjects for examination if brought young, but then only for a short period. They can suggest nothing as to the possibility of progress in evolution. Those he studied, owing either to un congenial surroundings, or, as he thinks possible, to the attainment of sexual maturity, soon tended to lie about all day in a sort of slumber and only roused themselves at meal times or when a special stimulus was applied.

The following is a brief description of some of the principal tests to which the animals were submitted under the least complicated conditions.

Sultan, a young male chimpanzee, was tested by suspending a basket containing bananas 2 metres from the ground by a cord passing over a pulley fixed to the roof. A loop at the free end of the cord was hitched over the branch of a tree—Sultan knew the basket and what was in it. When left alone he at first exhibited excitement and after gazing at the basket climbed the tree then without attempting to detach the cord he jerked on it until a banana fell. Having eaten it he returned to the tree the cord had meanwhile been fixed and he tugged on it until it broke. Next a basket containing stones as well as fruit was made to swing so that at the end of one excursion it came near a scaffold. Three chimpanzees were let in to view the swinging basket. Grande, one of the older chimpanzees, first leapt at the basket from the ground and missed. Chica, an active young female, watched and then suddenly climbed the scaffold stretched out her arms and caught the basket all within a minute. On a repetition of the test Grande at once imitated Chica and caught the basket. The third chimpanzee followed after getting over shyness as did other chimpanzees after periods of indifference or complaining.

An alley was constructed blocked at the end by bars through which some food could be seen but in order to get at it was necessary either to turn back to the entrance of the alley and pass round a corner or to climb over the obstruction. The chimpanzees achieved the task when once they had learnt the route but they did not succeed so quickly or so well as a dog nor as well as a girl aged 15 months just able to walk but they did better than hens.

Sultan was brought from the outside through a doorway along a passage then through a second doorway into a room. He there watched a banana thrown out of a window and the window closed by a shutter. He at once turned round passed out of the room through the passage and the outside doorway, and thence by "noth" turn reached the banana lying under the window.

Tested by placing in sight but out of reach food with a string attached to it the free end being within reach chimpanzees understood the use of the string but a dog did not. The chimpanzees can become adepts in the use of sticks to draw food into reach, and also learn to use a cloth to flap the food towards them.

The chimpanzees were ready to play with empty boxes. Six were

put together into a cage the walls of which were too smooth to climb. Food was suspended from the roof about 2½ metres from the floor. All six first tried to reach it by leaping. Sultan soon ceased, paced restlessly up and down, and then five minutes after entering the cage dragged a box under the food, sprang upon it, and tore down the banana, all in a few seconds. With further practice Sultan when one box was not enough, came to place a second on top of the first and to climb upon it. The other chimpanzees learnt by watching Sultan. Sultan eventually placed a third box upon the second. Another chimpanzee (Grande) learnt to pile four boxes one upon another in order to reach the objective. Instead of such a construction Sultan tried to induce the keeper to stand underneath so that he might mount on his shoulders.

The chimpanzees made use of a stick as a spud to dig up roots to rid in raising stone in the search for insects and to poke into holes in trees to get at grubs. The following were devised as tests of memory of position. Sultan, while sitting alone in a barred cage watched a pear being buried in the sand 140 metres from the bars to the depth of some centimetres, and the sandy surface smoothed over until the spot was unrecognizable. After an interval of five minutes Sultan noticed a stick lying at some distance outside the cage whereupon he seized the observer's hand and motioned him in the direction of the stick. Sultan repeated this gesture at intervals for half an hour when the stick was brought within his reach, he at once poked it through the bars and scraped away the sand exactly over the position of the pear. The next day the pear was buried 130 metres from the bars and 2 metres to one side of the previous spot. Sultan watched the process then turned away and occupied himself otherwise. One hour later a keeper threw a stick into the bare of the cage. Sultan at once picked it up and began to scrape off the sand at first about 30 cm to one side then over the precise spot and brought out the pear. Three days later a heap of fruit was buried while the apes were looking on afterwards they went to their sleeping quarters, in their absence the surface was smoothed over the fruit and some more holes were dug a few metres away but left empty. The next morning sixteen and a half hours after the apes had seen the fruit buried they were let out and Sultan proceeded in a straight line to a spot 60 cm from the right one. He scraped away the sand until he came to the buried ground the others acted similarly but after a pause they discovered the right spot. Sultan also learnt when given two bamboo rods, one thinner than the other to push the thinner into the larger and use the extended rod for pulling a banana to him. They knew how to use a pole both for heaving down fruit and as an aid in leaping and also how to clamber up a bamboo pole using both hands and feet. At first they fell with the pole but learnt either to seize the fruit or to swing off the pole on to a beam or branch of a tree.

The foregoing experiments resemble one another in this that to get at the desired objective, after failure of direct attempts, the animal had to adopt an alternative, which had been placed more or less distinctly within its range of vision while gazing at the object. A perusal of the book will impress the reader with the difficulties of instituting in this way a comparison between the mentality of chimpanzees and that of human beings, whether children or adults.

This remark applies all the more strongly to *Chimpanzee Intelligence and its Vocal Expressions*.² In the first part of the book Miss YERKES describes the traits of young chimpanzees, including the sounds they make, concerning which she observes "Vocal reactions are frequent and varied in the young chimpanzee, but speech in the human sense is absent." In the second half Miss LEARNED makes use of a musical notation to express what the utterances of the chimpanzees sounded like, and in a final chapter correlates these sounds with what she concludes the animals meant by them. A list is given of the sounds turned into words as if elements of speech.

THE PHYSIOLOGY OF MIND

A second edition of Dr FRANCIS X DERCUM's volume on *The Physiology of Mind*³ has recently been published. The book was originally written in the form of a continuous essay, but the present edition has been improved by the division of its contents into chapters, the work has been completely revised also and contains much additional matter. A chapter has been added dealing with the nervous system in the light of Einstein's interpretation of energy, and in an appendix the author subjects Freudism to criticism, and reveals himself as an uncompromising opponent of psycho-analysis.

¹ *Chimpanzee Intelligence and its Vocal Expressions*. By Robert M Yerkes and Blanche W Learned. Baltimore. The Williams and Wilkins Company. London. Baillière Tindall and Cox. 1925. (Cr 8vo pp 157 2 plates 17s 6d net)

² *The Physiology of Mind. An Interpretation based on Biological Psychological Physical and Chemical Considerations*. By Francis X Dercum. AM MD PhD. Second edition. 1st Philadelphia and London. W B Saunders Company. 1925. (Post 8vo pp 287 16 net)

³ *The Mentality of Apes*. By Wolfgang Kohler. Translated from the first edition by E.H. Wier. 1925. International Library of Theoretical Psychology and Scientific Method. London. Hegan Paul Trenc. Frutcher and Co. Ltd. 1925. (12s 6d)

Dr Dereum aims at developing the view that a study of mind from the standpoint of the physiology of the nervous system leads to the conclusion that the "physiology of mind" embraces what is ordinarily meant by "psychology." An excellent outline is given of the evolution and physiology of the nervous system, and there is no doubt that a knowledge of the neuro-physiological basis of action should be an essential part of the equipment of the student of human behaviour. At the same time it may be questioned whether psychology can be regarded merely as a department of brain physiology. Psychology, owing to the nature of its subject-matter, has methods of investigation and a terminology peculiar to itself, and it is obvious that we cannot understand, predict, or control the behaviour of a human being by making the changes occurring in his nervous system and the paths taken by stimuli the primary subjects for consideration.

The essay as a whole is stimulating, suggestive, and informing. The earlier chapters, dealing with the development and morphology of the nervous system, would be most helpful to those readers with only a slight knowledge of the anatomy of the nervous system if the text had been illustrated by diagrams.

THE ETIOLOGY OF DENTAL DISEASE

MR ORAN STARR writes in his book *Lamarck-Darwinism and Dental Disease*, "The great thought intended to be threaded through this book from first to last is that every physiological action, every anatomical structure, and every characteristic of living substance is, or will be, explicable by Lamarck-Darwinism with advantages to hygiene and health."

In pursuance of this thought he devotes the first two hundred pages of his book to a somewhat rhetorical apology of the inheritance of acquired characters and of the effects of use and disuse. The development of life from its first beginning as a protoplasm (which is described as an "energy") to man with all his dental ills, is sketched as in obedience to six great laws, two of which are Lamarck's laws of use and disuse and inheritance of acquired characters. No other idea on evolution can be entertained—it is, he says, "mere foolishness to try to account for the peculiarities of heredity by overcrowning the poor little germ and sperm cells with determinants, unit-characters, dominants, memoirs, and every conceivable kind of imaginary entity, and try to prove a theory by mathematical formulae."

When we come to teeth as a concrete example of the effect of disuse we read, "the hard work thus thrown upon young teeth would soon change their shape"—an obvious impossibility except in so far as they are ground down and destroyed by overuse. Disuse does not seem to fit in well as an explanation of dental errors.

In his discussion of protrusion the author makes more effective application of his thesis. Cooked food, he thinks, vitiates the function of mastication, and the tissues supporting the teeth may therefore be expected to suffer from disuse. But even so his case is not yet proved. Cooked food may not need mastication, but the act is performed just the same and with equal vigour as when uncooked food is eaten.

When considering the immediate causes of dental errors and protrusion the author finds himself in agreement with what we believe to be the opinion generally accepted to-day, that both are due to a common state—that is dent of the teeth. Resistance to protrusion could be raised by eating more uncooked food and so ingesting more vitamins (or, as the author prefers to call these elusive substances, "anti-toxins"), and both diseases could be avoided by disuse of sticky foods. "Gum must not be ground except by dental machinery. Food must not be digested except by living tissue." Whether we agree with the author that all the dental troubles of modern civilized communities are the result of disobedience of the Lamarck-Darwin laws of evolution or whether we regard

ourselves as governed by an evolutionary law which of itself necessitates disobedience of the Lamarck-Darwin precepts, we must be in hearty agreement with him in calling for the use of less sticky food—and, we may add, in his admiration for Lamarck!

GUY'S HOSPITAL REPORTS

THE third quarterly instalment of the seventy-fifth volume of the *Guy's Hospital Reports* contains twelve articles covering such a wide area that it is difficult to imagine any medical man failing to find at least one that would specially interest him. "Kerfs as a medical student" is the subject of an attractive article by Sir William Hale-White, who not only reproduces the life and chief actors in the Guy's medical school when Kerfs was there, but breaks new ground by analysing the poet's notes of lectures by Mr C—, who is fairly proved to have been Astley Cooper, rather than Henry Cline, jun., for both then taught on closely allied subjects at the same time. The next two articles are on physiological subjects. Dr J M H Campbell deals in detail with the weight, vital capacity, pulse rate before and after exercise, and physical fitness in health of the eighty Guy's students who were examined by means of fractional test meals and x rays and reported on in previous papers.

The U-tube manometer test introduced by the Rev Stephen Hales in the eighteenth century, utilized in the great war by Wing Commander Martin Fleck for estimating the fitness of airmen, and now in more general use for testing industrial efficiency, is the subject of a paper by Mr E C Warner and Mr W B Hambly of the physiological department, who provide explanations of the variations in the blood pressure and pulse rate while the column of mercury is held up by expiration. Mr A A Osborn contributes a clinical study of fifty six cases of renal nephritis in children and young adults, which were followed up for periods of one and a half to twenty-two years, and finds that at least 55 per cent were due to infections of the upper respiratory tract, generally the tonsils, and that 36 per cent did not recover completely. A case of exceptionally high eosinophilia in hydatid disease (68 per cent) is recorded by Mr C A Hampson, and a fatal case of tetanus with an incubation period of seven days in which the bacillus was obtained from the healed wound is put on record by Mr I March and Mr R B Fawkes. Mr R P Rowlands follows up his article on appendicitis in the last number by an account of the operative treatment of this disease.

The editor, Dr A I Hirst, whose guiding hand is manifest in other articles, contributes three under his own name in a continuation of his account of massage and remedial exercises in medicine he deals with the treatment of the abdominal and pelvic muscles in visceroptosis, rectal and uterine prolapse, and constipation, the rationale and nature of the remedial measures are clearly set out—for example, in severe visceroptosis walking on all fours, as first described by Leon Meunier, is recommended as specially useful. Abdominal massage should not cause pain, if it does it is an indication either that the condition is unsuitable or that the method is unskillfully employed. The consideration of this is supplemented by an account of genital prolapse in women by Mr H B Butler. The editor also describes, with diagrams and figures, two cases of a diverticulum from the lower end of the oesophagus—a much rarer condition than pharyngo-oesophageal pouches, these two cases bring the total up to twenty-nine, four of which were engrafted on to dilatation due to achalasia. Together with Mr P J Briggs, radiologist to the New Lodge Clinic, he reports a case of an anterior pharyngo-oesophageal pouch causing dysphagia. From careful observations on von Piquet's cutaneous tuberculin test, Dr A J Komisar shows that there is a difference in the positive results obtained in obviously tuberculous patients and in the 81 per cent of persons who appear clinically healthy.

NOTES ON BOOKS

WE are glad to note that Professor J C PHILIP's book on *Physical Chemistry* has reached a third edition.¹⁰ It has been looked on as a useful book from which to gain a clear idea of what is meant by osmotic pressure, permeability, electrolytic dissociation, and adsorption, to mention only a few of the technicalities of physical chemistry which have a direct bearing on medical science. For his chapters on colloidal solutions Dr Philip must have earned the gratitude of many a student, especially because of his knack of actually removing stumbling blocks and not merely directing the way to a well trodden path round them. The third edition takes much the same form as its predecessor, though some new matter has been added. The book does not seem to be much larger and is arranged in the same way as before.

After a lapse of twelve years E TOROK and G H GROUT have re-edited their *Surgery of the Eye*.¹¹ Several new operations have now been included, and many which received only brief notice in the previous edition, but have since come into general use, are described in detail. The illustrations were a strong feature of the first edition, and their number has been increased. For the photographs, some of which were indistinct, have been substituted drawings of a semi-schematic character, which admirably serve their primary purpose of conveying a clear picture of the procedures described. The book is intended for the student and the beginner, and the authors have succeeded in their aim of presenting the essentials of the subject in a simple, clear, and concise manner. They describe in detail each step of the more common procedures, survey the indications and contraindications for them, provide notes on the preparation of the patient and on the appropriate instruments, and give advice as to the after-treatment, finally, they consider the possible complications, immediate and remote. In their choice of considerations for examination on the licentiate is described without reference to any of the methods of establishing drainage into the nose. There is a very complete index.

The fourth of the statistical handbooks¹² issued by the Health Organization of the League of Nations deals with Spain. So far as census taking is concerned the Spaniards were in the field long before we were, their first census was in 1594. The record, indeed, shows considerable improvements, and in one respect—the compulsory notification of stillbirths—Spain is in advance of us, but the certification of causes of death still leaves much to be desired. The handbook remarks that, having regard to the legal requirements and the fact that in a population of 22 million there are some 26,000 registered medical practitioners, it is probable that few deaths escape registration. But the proportion of deaths assigned to ambiguous headings is very large, and "in any case of doubt affecting the death of a person aged 59 years or over, the cause of death is usually ascribed to 'senility'." This practice renders it doubtful whether addition to bull fights can really explain the relative immunity from cancer enjoyed by the Spaniards.

Mr R T CUNTER's little book on *Historic Instruments for the Advancement of Science*¹³ is a handbook to the Oxford collections prepared for the opening of the Lewis Evans collections on May 5th, 1925. It opens with an account of the old Ashmolean Museum, which the author claims to be the first public museum of natural history in Britain. The instruments described include astrolabes, dials, nocturnals, globes, calculating apparatus, water-wisdoms, as early taximeters were called quadrants, theodolites, magnets, compasses, telescopes and microscopes. Of special interest to the medical reader is the account of Marshall's microscope for viewing the circulation of the blood which was made in 1693.

In an address on the problems and aims of epidemiological research of the founding of the Dr FRIEDRICH WOLTER or Hamburg, who pays a tribute to the memory of the late Dr Richard J Reece emphasizes the importance of giving

consideration to factors other than those connected with bacteriology, and declares that the doctrine of the epidemic constitution put forward by Sydenham and supported by Pottenger in the case of typhoid fever and cholera is "the Ariadne thread which will serve as a guide in the labyrinth of theories and hypotheses connected with epidemiology."

Dr GRIFFITH's manual on *The Care of the Baby* seems likely to rival Dr Charvase's *Advice to a Mother* in the frequency of its editions, the seventh¹⁴ is a volume of nearly five hundred pages. The ground covered is immense, beginning with the mother's health before the baby arrives, including almost all the diseases from which children may suffer, and concluding with appendices which contain nineteen formulae for making modified milk, and a long list of drugs with the doses suitable for a child 1 year of age. From the evident popularity of the book we may presume that American mothers are able to read all about the dreadful diseases that may affect them or their children without developing an excess of anxiety. We think that too much has been attempted, and that the descriptions and details are overdone. Perhaps the book has its uses in the hands of intelligent mothers living in places where doctors are not easily summoned.

A new edition of the *Pharmacopoeia of the London Hospital*¹⁵ has been issued, and contains a large amount of information very clearly set out. A table of the approximate equivalents of imperial and metric dosage will be found valuable and convenient. Separate series of formulae are provided for children, dental cases, ear and throat cases, and ophthalmic cases, and a comprehensive list of antidotes to poisons is another useful feature of the book. A new edition of the *Pharmacopoeia of the London Temperance Hospital*¹⁶ has also been prepared. The free interweaving of the book is a useful feature. In addition to the list of general formulae a helpful series of instructions to patients is included, presumably with a view to assisting the house staff in giving advice.

MEDICAL AND SURGICAL APPLIANCES

Arrest of Haemorrhage in Epistaxis. Dr CHARLES R PORTER (Great Beckenhamsted) writes: The frequency with which the busy practitioner is called to cases of epistaxis and the time spent in the usual routine treatment of such cases suggested the use of the epistaxis clip illustrated below.

It is designed only for haemorrhage from the anterior portion of the septum, which in an experience of twenty years of general practice seems to be the most common site. The large majority of haemorrhages occur in patients over 50 years of age, and are associated with arterio-sclerosis and increased blood pressure. The simple expedient of compressing the naves just below the nasal bones with the thumb and forefinger is equally efficient but hardly preferable for more than ten to fifteen minutes. The idea of the clip came from using a small Mason's gag now old fashioned, using the handles as the compressors and adjusting the ratchet and piston to modify the pressure required.

Dr Porter states that the advantages of the use of the clip are: (1) The adjustment is simple and can be learnt by the patient or by any untrained person in the household in a few minutes. (2) The weight of the clip reminds the patient to keep quiet in the position of recumbency with the head raised to a comfortable position on pillows thus enables a book or paper to be read. (3) The complete arrest of haemorrhage restoration of the patient's confidence and relief of the friends' anxiety. (4) The obviating of the uncomfortable procedure of plugging the nostril, or of cauterization both of which require time and apparatus and increase the apprehension on the part of patient and friend. (5) The medical man can leave the patient for an hour or more after a visit of five to ten minutes. This idea has been neatly and effectively carried out by Messrs Allen and Hanbury, 48 Wigmore Street W1. The accompanying sketch shows the clip in position.

Nota et Vetera.

EARLY CHARTERS WITNESSED BY MEDICAL MEN

SIR NORMAN MOORE in his FitzPatrick Lectures published in 1908, gave some examples of medical witnesses to early charters, and cited in the appendix eight Royal charters which were witnessed by a physician, by name Grimbald, as well as an early charter to St Bartholomew's Hospital, which was witnessed by John of London the physician. I am indebted to Dr George C Percley for calling my attention to these facts. In this paper I give some further examples of medical witnesses.

In the *Monasticon* (vol 4, p 150, edition of 1823) under Walden Abbey, Essex, in the charter of Geoffrey de Say, the eleventh out of fourteen witnesses who are named is Magistro Thoma Medico. Walden Abbey was founded by Geoffrey de Mandeville, first Earl of Essex, in 1136. The founder's sister, Beatrice, was the wife of William de Say, and the grantor of this charter was her second son. In volume 7 of the same work (p 659), under the Hospital of St John Baptist, Coventry, in a *Confirmatio dicti Domini Edmondi super Fundationem, Possessiones et Dona Prædicta*, the third witness out of six mentioned by name is Magistro Ricardo Medico. This grant was passed early in the reign of Henry II in the priory of Laurence of Coventry Monastery (1144-1179). There may be some other examples in the *Monasticon*, but I have not come across them.

Two very interesting early charters are given in volume 10 of the publications of the Pipe Roll Society. This volume consists of a series of ancient charters, royal and private, prior to 1200 (Part I), it is edited and annotated by Dr J Horace Round.

The first of these early deeds, is a confirmation by Henry I of grants made to Lewes Priory by William de Warenne, 1st of Surrey, the fifth witness is Grimbald. This charter is not included in Norman Moore's list.

Notum sit presentibus et futuris quod ego Henricus [] locum concedo dedit et sanctis apostolicis Petri et Paulo ad locum sancti Pancratii pro anima patris mei et matris et pro [] hute aumre mere et uxoris mee Matildis re filii mei Willelmi donationem quam Willelmus de Warenna comes subregne sancto Pancratii dedit. Sciatis ecclesiam de Bistelmestuna et ecclesiam de Hingelstuna et ecclesiam de Cletuna et Capell[] de Kiemela et ecclesiam de becca et ecclesiam de eidingelegr et quadrigenta solidatas terrae de illa soca de gelungelham pro decima decuriorum de placitis suis et decimam faciu sui e molendinum unum apud meeng[] cum quatuor a[] et dimidiam hidam terrae in bistelmestuna et rusticum alium nomine brimerum cum terra illa quam tenebat de Radulfo filio Warrini et tertiam partem Willelmus de grinnosa villa tenebat de predicto comite in erchelham et decem solidatas terre e octo denaritas quas Hugo de grinnosa villa dedit aucto Pancratii in testem pro decimis terrae suae. Testibus Radulfo cancellario Ricardo de capellano Euciarlo filio Roggeri comitis Johanni debaroco et Grimbaldio medico Henrico de ubino et Rodberto de [] Rodberto de Gomeri Willelmo de petroponto [] Ricardo lupello.

The learned editor in his notes to this charter says that this must be earlier than the date of Queen Maud's death in 1118. "It cannot, however, be earlier than 1107, which is recognized as the earliest year in which Radulph appears as Chancellor."

Richard de Capella became Bishop of Hereford in 1121, Fecard son of Earl Roger of Shrewsbury by his second wife was also of the King's chapel and was consecrated Bishop of Norwich in 1121. John de Bayeux was the natural son of Bishop Odo the Conqueror's half brother and was another of the King's clerks. Henry de Albini was the founder of the house of Albini de Caynho and William de Pierpont was probably son of Godfrey de Pierpont a Domesday subtenant of Warenne.

In the grant itself, Round identifies the churches of Brighton, Hangleton, Clayton Keymer, Barcombe, and Avingly, the tithe of lry, and the half hide at Brighton, and Bithmei the Villen with his land, and the mill at Meeching (now Newhaven) with its four acres. The charter of Ful William was granted "for the souls" of his father (William), his mother (Gundrada), and his brother

(Reginald), the last was therefore dead at the time. He appears to have been living at least as late as 1106.

The second charter is a grant by Ralph, Archbishop of Canterbury, to Lewes Priory of an annual render of thirty-six loads of beans, known as "circescet," from his Archepiscopal Manor of Pagham (Sussex).

Radulfus cantuariensis Archepiscopus Radulfi circestrensi episcopo atque omnibus fidelibus suis salutem. Scitis me dedisse fratribus nostris monachis videlicet sancti pancratii de launs semper in posterum deinceps habendum illum redditum fabarum quem retinui et habeo in domo nostro apud villam nostiam pagham et vocatu circescet et habebunt inde singulis annis xxxvi sumas de fabis. Testibus Theodrico priore cantuariensis Hugone monacho Felice monacho Anfrido dapifero Rodberto de cerecio Rogero de sancto albano Hufrido clerico Rollando medico Roberto filio Riculfi.

Round notes that this charter must be previous to the death of Archbishop Ralph in 1122. Conrad was appointed prior by Anselm in 1109, and was still prior in 1119. The name of Theodoric of Canterbury does not figure on the existing list of priors, but this fact much proves the incompleteness of such lists. Of "circescet" Round says as follows:

"This notoriously obscure due is described by Dr Stubbs as a sort of commutation for first fruits paid by every householder. The best account of it however, will be found in the special appendix on the question in Kemble's *Anglo Saxons in England*. It occurs with various spellings, some dozen times in Domesday, but not in the case of Pagham though the account of that manor is a full one. The inference is that the silence of Domesday nowhere proves its non-existence. At Pagham it was probably, at the time of the survey included in the total render (*redditus*) but subsequently returned in hand (*i.e.*, excluded from the *firma*) by Archbishop Ralph. In Domesday we find the due generally commuted for money. In Worcestershire however it was paid in kind and as here at Pagham, in loads (*sumae annonae*) one being due from each hide. Here the rate was nearly the same Pagham having been assessed at fifty and then at thirty four hides.

At Pagham an extra couple of loads of beans were thrown in. "The grant also illustrates the power of a life-tenant of ecclesiastical property over immovables held in *dominio*."

It only remains for me to add that if any mistakes are found in the extension of the few quotations in the Latin of these deeds they must be ascribed to my ignorance of the language and not to Dr Round.

R R JAMES, F.R.C.S.

LUNACY AND MENTAL DEFICIENCY

REPORT OF THE BOARD OF CONTROL FOR 1924

ON January 1st, 1925, the number of notified insane persons under care in England and Wales was 131,551 in increase of 1,217 over the number on January 1st, 1924. It is pointed out in the eleventh annual report of the Board of Control that this increase has no necessary connexion with the incidence of mental disorder in the general population, but is merely the net balance as between the admissions and the combined deaths and discharges. The relative percentage distribution of the sexes—males 43.9, females 56.1—was the same as in the previous year. The recovery rate, calculated upon the direct admissions, was 34.86 per cent. The death rate was again very low, being 7.62 of the daily average number resident.

Classification of Mental Patients

The Board regards the question of classification as one of particular importance. Strict classification of the patients according to their form of mental disorder is for many reasons undesirable. What is of special importance is the segregation of recent and probably recoverable patients. They would be shielded from the possibly adverse effects of association with cases of confirmed mental disorder. They would be in an atmosphere of hope and recovery. The provision of a nursing staff on a liberal scale would afford an opportunity of providing individual attention and treatment, and, locked doors being dispensed

¹ Eleventh Annual Report of the Board of Control for the year 1924. London: H.M. Stationery Office, Adastral House, W.C.2, or through any bookseller. 1925. 12s. 6d.

with, a feeling of restraint and detention would not arise. To this end the Board renews its policy of separate admission hospitals, and, while avoiding the stereotyping of any particular design as a model intends to set out the structural requirements which should be borne in mind in the planning of such hospitals. Those patients in the admission hospital who have improved enough to permit of considerable relaxation of supervision should be withdrawn without delay from the presence of others with active mental symptoms, and those in whose case the chances of discharge are favourable should be kept apart from patients whose stay is likely to be protracted. It is accordingly the Board's desire to see at every mental hospital, ancillary to but sufficiently distant from the admission hospital, a detached convalescent home allowing free ingress and egress, and made as homelike as possible. Recovering patients would pass to the convalescent home without having experienced any sense of restraint or detention.

Open-door Wards and Parole

Quite apart from the convalescent and recoverable patients there are large numbers whose happiness is greatly affected by the existence or absence of the privileges of open-door wards and of parole. In nearly every mental hospital there is a community of able-bodied, trustworthy, and industrious patients who require long continued care and supervision because of persistent or recurrent mental symptoms. Their supervision, however, need not be rigorous, and they can be trusted with liberty during non-working hours to walk about the grounds. This is best arranged by a classification, which includes villas or wards administered on the open-door principle, to which none but parole patients are sent. This is not only desirable for the sake of the parole patients themselves, but also acts as a direct incentive to others to exercise self-control and to fit themselves for promotion to the open-door unit. The Board has now for many years given every encouragement for the provision of such facilities, and expresses gratification at finding their adoption in over 80 per cent of mental hospitals.

Visiting Specialists

The Board attaches great significance to the movement towards the employment of skilled specialists in various branches of medical work, not merely occasionally, but as part of the routine arrangements. The Board sees in this the means both of preventing mental hospitals working in a groove and of maintaining an active and mutually advantageous link between psychological and general medicine, besides the obvious advantages to the patients. Doctors who take up permanent resident posts in mental hospitals ought not to be expected to undertake surgical operations or to possess a corresponding competency in branches other than those of general and psychological medicine. Visiting committees are urged to appoint specialists who will regularly visit at prescribed intervals, and who will also be available for emergency calls. At some hospitals it happens that one or more of the resident medical staff has special competency in certain specialist services but however great his competency, the Board regards the placing of reliance on his services as a mistaken policy, and one which causes the sacrifice of time which can ill be spared from his recognized duties.

Open air Treatment and Hydrotherapy

The value of rest in bed for the treatment of active and acute mental symptoms is generally recognized, but of more recent growth is the opinion that the beneficial effect of this rest in bed is greatly enhanced if it can be laid in the open air. Open-air treatment in bed is a powerful tranquilizer and a valuable corrective in cases of insomnia.

Surprise is felt that in mental hospitals in this country hydrotherapeutic methods, speaking generally, are but little employed, and this all the more so inasmuch as in almost every treatise, modern as well as old, upon the treatment of mental disorder mention is made of various forms of bath as being admittedly powerful therapeutic

agents for their sedative effect in controlling excitement, their soporific influence in insomnia, their action in eliminating effete products, and their tonic effect in conditions of vasomotor stasis.

In the late fifties some mental hospitals were quick to see the utility of the recently introduced Turkish baths, and caused them to be installed. They appear now, however, to be but little used, owing perhaps to administrative difficulties. Treatment by the use of the wet pack is also seldom employed. This may be partially explained by the fact that the Commissioners felt it necessary to include it among forms of mechanical restraint. Under the new regulations of January 7th, 1925, it is no longer so regarded. The form of hydrotherapy now most usually employed is that of the "continuous bath," and is one of undoubted service.

Facilities for Examination

The relationship between mental and physical conditions is too intimate to warrant the absence from a properly equipped mental hospital of any recognized means of investigation. A growing recognition of the important part played by certain bodily conditions whose absence is often not determinable by bedside examination make it imperative that every mental hospital should possess at least a small clinical laboratory. The employment of a trained laboratory assistant to work under the direction of the medical staff is essential. The Board is satisfied that there is an increasing tendency to develop laboratory facilities in mental hospitals. Any institutions also run but be considered a necessary part of their outfit. Apart from the wisdom of a routine use of serum examination on admission and after any accident and trouble, there are many important spheres for its use in the investigation of septic foci, in the localization of intracranial growths and for therapeutic purposes. Considerable stress is also laid in this report on the necessity for the provision of clinical rooms in the wards where patient and doctor can be uninterrupted and not overheard, such conditions being essential for the adequate examination of mental states and for treatment by psychotherapeutic measures.

Coroner's Inquests

In a communication to the Board last November from the Coroner for the Southern District of the County of London it was pointed out that, especially in a district where there are a number of institutions for mentally disordered patients, allegations are liable to be made in the investigation of which the presence of someone with practical knowledge of the management of such institutions, but not connected therewith, would be an advantage. The Board has acquiesced in the suggestion that it should nominate someone with the necessary experience to act as assessor with the coroner on the bench.

Mental Deficiency

A considerable section of the report is devoted to a consideration of the present grave lack of accommodation for all types of mental defectives. Urgent cases have been, and are being, discovered for whom no vacancies in existing institutions are available. The country in this respect has come for the time being to the end of its resources, and unless the local authorities give immediate consideration to this matter the beneficent intention of the Mental Deficiency Act will be hampered and will almost cease to operate. Cases illustrative of the urgent need of such accommodation are set out in detail.

This report should be read by everyone interested in the mentally disordered or mentally deficient person. It illustrates how particular is the care exercised by the Board of Control in all matters appertaining to the welfare of these patients, and how zealous it is in advocating whatsoever measures may temper their unfortunate state and promote their eventual recovery. The reasonableness and practicability of the Board's suggestions are unquestionable, and should, wherever and as soon as possible, be made effective.

British Medical Journal.

SATURDAY SEPTEMBER 26TH, 1925

THE PRESENT POSITION OF PATHOLOGY AND BACTERIOLOGY

The subject of the discussion at Bath which we report in full at page 554, on the present position of pathology and bacteriology in this country was chosen for consideration by the Pathological Section of the British Medical Association's Annual Meeting because many pathologists thought that the observations on this branch of medical science made in the report of the Medical Research Council for 1924 called for some reply. It will be remembered that in the quarterly review of the progress of medicine included in that report, generous praise was meted out to the sciences of physiology and biochemistry but a less approving eye scanned the achievements of the pathologist. The abundant harvest yielded by physiological research was contrasted with the apparently meagre fruit of the pathological tree of knowledge and the conclusion was reached that the position and progress of these sciences [pathology and bacteriology] on which so much of the current work of medicine depends, cannot be regarded as satisfactory. In a leading article on February 14th last (p. 319) we made some comments on certain specific causes to which the Medical Research Council's report attributed the seeming decline in pathological research more particularly with reference to the organization of the bacteriological laboratories of universities, hospitals, and public health authorities. But this is only one part of a very big question as is clearly shown by the frank opinions expressed during the debate at Bath.

It is interesting to notice in the first place that many prominent pathologists find the comparisons of the Medical Research Council's report unfair and its criticism unjustified. Dr. Adwright and others remarked that it seems idle to discuss whether physiology or pathology is the more fertile field to cultivate, since the distinction between them is arbitrary and cannot be clearly defined. The biological research worker is becoming in Dr. Tiedemann's words, increasingly difficult to label and much of what is called modern physiology is in truth experimental pathology. But even accepting conventional distinctions and putting aside the question whether it is possible accurately to estimate the achievements of any science over such a short space of time several speakers at Bath challenged the judgement of the Medical Research Council's report on the ground that it is inconsistent. Therein it will be remembered the science of pathology is declared to have suffered because of a too close concentration on its practical service to medicine and the practice of applied pathology within the universities is wholeheartedly condemned. On the other hand the report traces the success of physiologists to the fact that they have at last become practical people. The war pulled them out of their shell, so to speak, for the pressing claims of sailors, soldiers, and munition workers brought the physiologists increasingly to their proper place within the fields of preventive and curative medicine. This closer union is said to have brought many benefits

to practical medicine and physiology alike for the stimulus of urgent problems, instead of filling men with from the idle pursuit of knowledge for its own sake, was found to freshen their interest and to suggest new clues for further pursuit by theoretical inquiry. Upon this Professor M. J. Stewart observed that it did not appear that what was sauce for the goose was equally sauce for the gander.

Whatever differences of view there may be as to the achievement of pathological research the speakers at Bath, almost without exception admitted that the organization of pathological services in this country calls for many changes and owing to this defect in organization research work has been greatly hindered. Conditions of work vary in different parts of the country and in different laboratories such as those of universities, institutes, and hospitals and it would be hard to formulate any detailed plan of general application to remove the disabilities of which pathologists complain. But judging by the opinions expressed at Bath and elsewhere when this question has been discussed pathologists in all parts of the country are dissatisfied with their status and with their facilities for doing research work.

On the question of the status of the pathologist Dr. Tiedemann's words may well be quoted. Speaking of opportunities and leisure for research he says:

There can be no guarantee, however, of then [pathologists] securing those conditions until law and medical appreciation of the pathologist's place in the scheme of things has very materially risen. Pathologists and bacteriologists have too long suffered from the clinician's conception of them as purely hewers of wood and drawers of water for their patients' benefit. There can be no doubt that the best pathological service can be realized only when ward and laboratory or patient and laboratory are brought as near as possible and mutual consultation on equal footing can be arranged. This question of status is intimately bound up with that of the training of pathologists. To become skilled in all branches of pathological and bacteriological laboratory work calls for a long training in technical methods and very wide reading. The need for this apprenticeship is often overlooked by committees in charge of pathological appointments, and it might improve the status of the trained pathologist if he could point to some recognition of his specialization comparable to the F.R.C.S. diploma of the surgeon or M.R.C.P. of the consulting physician. The D.P.H. though certainly a useful training for some branches of laboratory work should not be looked upon as evidence of competence in pathology whose province is much larger than that covered by the pathological requirements for the diploma in public health.

But unquestionably the keenest grievance of the pathologist arises from interference with his facilities for research work. If he holds a whole time post he is expected to spend all the day teaching and carrying out routine diagnostic tests, and to do his research in the evening. Not only is it impossible to prosecute research under such conditions but if long continued, the drudgery of routine work and teaching stifles the impulse to investigate and the pathologist is deprived of the chief attraction which drew him to laboratory life. The obligation to attempt to further scientific knowledge should be recognized by everyone who holds a pathological appointment and enjoys the facilities of a well equipped laboratory. So, too the obligation to encourage and secure leisure for these researches should be recognized by all medical and law committees of management.

COCAINE SUBSTITUTES

For the last twenty years the medical profession has been in search of some efficient substitute for cocaine. Cocaine is used almost entirely as a local anæsthetic, and in one sense is nearly ideal, since it acts both by injection and when painted on mucous surfaces, also it constricts blood vessels, and is not sufficiently irritant to make this factor of moment. But after absorption cocaine exerts on the cerebral cortex a stimulating action, which is especially pronounced in fatigue and in the condition of neurasthenia, it whips the flagging nerve cells into activity, and induces a condition of exhilaration or excitement in which the individual may lose his sense of responsibility. The sudden relief from mental fatigue, from worry and forebodings, is so decided that the sufferer readily falls back on his pinacra on every trifling occasion, and before he knows of his fetters he is an addict. But besides this possible danger there is the immediate danger of sudden collapse and even death following an injection for local anæsthesia. A sudden and excessive absorption of cocaine may, after a very brief stimulation, produce depression of the cortex and medulla, resulting in a fall of blood pressure, feeble respiration, and all the symptoms of shock and collapse, recovery from this condition is often very slow. To some extent the *British Pharmacopœia* has been responsible for some of the cases, since the official injection contains 5 per cent of the alkaloid—an amount probably five times greater than is necessary. For this reason cocaine is now rightly placed among the dangerous drugs, and the medical profession is still seeking a substitute which, while possessing all the anæsthetic properties of cocaine, lacks its effect on the central nervous system and its toxicity.

Picaine and butyn both exert a central action like cocaine, but eucaine is too irritant, novocain and its substitutes do not act in reasonable amounts as local anæsthetics—that is, they will not anæsthetize the eye, urethra, and nose. It is therefore with pleasure that we welcome a new principle in connexion with surface anæsthesia propounded by Dr A J Copeland and Mr H E F Notton in the opening paper in this issue of the *BRITISH MEDICAL JOURNAL*. Many basic substances—cocaine, ethocaine, eucaine, and the like—act as local anæsthetics when injected subcutaneous in the form of some ordinary salt such as the hydrochloride, but cocaine is the only base of which the salts are known to act as powerful, and hence useful, anæsthetics of the mucous membrane of the eye, nose, urethra, and other sensitive areas. It has been noted, however, that the intensity of the action of cocaine salts can be modified by the addition of certain apparently inactive substances to the solution, and in this fact the germ of what appears to be a most useful discovery has been discerned.

The possibility of varying the intensity of action of a surface anæsthetic led to a consideration of what modifications in the state of the base accompany this change. Cocaine is usually applied in solution as its hydrochloride—namely as a salt with a strong acid, in such solutions the salt undergoes extensive electrolytic dissociation, and the base itself is largely present as an electro positive ion, giving the symbol C to cocaine the hydrochloride becomes C,HCl and the electro positive and negative ions existing in the dilute aqueous solution become

In a salt of cocaine with a very feeble acid such as boric acid, electrolytic dissociation is very largely

replaced by so called hydrolytic dissociation in which borate, C,HB is actually present as free base, C, and boric acid, HB. The variation in intensity of surface anæsthetic action of cocaine salts has been traced to the different action of the electro positive cocaine ion and of the hydrolytically dissociated cocaine base.

This is of interest in connexion with cocaine salts, but it becomes of paramount importance when applied to the use of ethocaine and other synthetic local anæsthetics which so far have not been known to exert useful surface anæsthetic action. Thus ethocaine hydrochloride (novocain) has practically no surface anæsthetic action—that is to say, the electro positive basic ion, E⁺H, does not effect local anæsthesia. On the other hand, an aqueous solution of the borate in which the base is present as such—hydrolytically dissociated—is a more powerful surface anæsthetic than cocaine hydrochloride in corresponding concentration. The surface anæsthetic action of ethocaine base under these conditions had not been observed previously, but it appears that ethocaine borate may almost entirely replace cocaine salts for surface anæsthetic purposes. This conclusion has a profound bearing upon the difficulties raised by the Dangerous Drugs Act in relation to the prescribing of cocaine for use as a surface anæsthetic, the borate under consideration is almost without toxicity, and its stimulant action on the central nervous system is said to be negligible.

The condition that maximum hydrolytic dissociation and minimum electrolytic dissociation should be established in solutions used as surface anæsthetics—and it appears that this is the condition to be fulfilled—is defined by the chemist as holding when the so called pH value lies at neutrality or on the alkaline side of neutrality—namely, at 6 or more. To ensure this great care is necessary in the manufacture of the borates, as the new salts are called, and for this reason strict chemical control has to be maintained.

The ultimate criterion of usefulness of the new principle enunciated by Dr Copeland and Mr Notton must, of course, depend on chemical results, and the medical profession will look forward to the publication of these with interest.

THE HANDLING OF FOOD

The manipulations to which so much of our food must of necessity be subjected excite alarm among two opposite schools of food reformers. One of these traces all manner of diseases, together with much vague ill health, to the changes which prepared food undergoes as the result of canning, bottling, cold storage, or chemical preservation. The chief of these changes is nowadays thought to be loss of vitamin content, and from this food reformer quite a comes the watchword that health depends on eating raw uncooked food. The other school of food reformers is disturbed by the thought of the prodigious population of microbes in mill, cheese, and so forth, and looks a glance at the naked exposure of the loaf of bread or fruit on the buffet, inviting the invasion of the omnipresent invisible foes of man. That some reforms are necessary in the methods of preparation and manner of distribution of food would be disputed by no one with a watchful eye, but in their devising protection may perhaps be needed almost as much from friends as from enemies. One danger with which friends threaten is that of overstatement, thereby engendering distrust in a public opinion notoriously slow to move. It is well, therefore—as was done in the discussion on this subject in the Section of Public Medicine at Bath, reported in full this week at page 560—to point

out to the one school that much of the manipulation of prepared food, such as processing, canning, and drying, need not necessarily destroy vitamins, and to the other school that the majority of the microbes likely to get into food from the air are harmless, and that the chief ones to fear are those which cause specific food poisoning. Since the specific germs of food poisoning nearly always come from diseased meat or from the handling of food by human sufferers or carriers of these bacteria, it is clear that the first points on which to concentrate are a wholesome source of food and a diminution of human handling. The ultimate ideal is of course, fresh food free from all preservatives, but such a diet is likely, for a long time to come, to be beyond the reach of all but the very wealthy. In the meanwhile, it is reassuring to know that food may be brought across the ocean still enriched with vitamins, and that meat in this may be just as nutritious as the carcasses hung in the butcher's shop. With the remarks of Dr. Goddard on the reckless exposure of all manner of foods in the shop and street every thinking person must be in full sympathy, and it is to be hoped that when the Ministry of Health has abated the evil of chemical preservatives in food this question of unnecessary exposure may receive more official attention.

X RAY THERAPY IN WHOOPING COUGH

Whooping-cough is a disease which may be said to be characterized by its ubiquity, its resistance to treatment, the distressing nature of its symptoms, and its liability to such serious complications or sequels as pneumonia, bronchitis, emphysema, tuberculosis, and otitis media. The prolonged course of the infective period makes preventive measures more than usually difficult, and therefore any method of treatment that seems likely to shorten the duration of the disease is worthy of notice. We have referred more than once before to the possibilities of x-ray therapy, and, in particular, to the work of Dr. H. I. Bowditch and his colleagues at the Boston Floating Hospital (*Epitome*, November 29th, 1924, page 424). More recently, Dr. J. W. J. Willcox described in our columns (May 16th, 1925, p. 921) successful results in nine cases treated by him along the Boston lines, but using a rather simpler technique. Dr. L. W. Smith, in collaboration with Dr. Bowditch and other American workers, has now published an analysis of 850 cases of whooping cough treated by x-rays, supplementing the original series of 300 cases. Comparison of the two series reveals a much smaller incidence of pneumonia in the second series, due, it appears, to the fact that earlier treatment has now been made possible by the spread of knowledge in America about the curative possibilities of x-rays in pertussis. In the present series the age incidence of whooping-cough is 88.2 per cent for children under 7 years, 30.5 for children under 2 years, and 8.4 for infants under 6 months of age. A positive bacteriological diagnosis was made in 180 of the 300 patients whose sputa were examined. The most infectious period appeared to be the catarrhal stage, and infectivity seemed to diminish very rapidly after the onset of the paroxysmal stage. No positive cultures were obtained after the second week of the whooping, which represented approximately the fourth week of the disease. From this the inference is drawn that the usual prolonged quarantine period of six to twelve weeks is unnecessary. Skingrams indicated the presence of characteristic pathological changes—namely, peribronchial thickening (most marked in the lower parts of the bronchial tree), enlargement of the mediastinal tracheobronchial lymph nodes (with a distribution unlike that of ordinary bronchitis), and the frequent appearance of mottling suggestive of com-

mencing bronchopneumonia. In the present series of 850 cases 700 patients received x-rays only, while 150 were in addition treated by vaccines. In 80 per cent of the cases treated by x-rays alone a pronounced diminution was observed in the number and severity of the paroxysms in a time interval which ranged from a few hours to a week or ten days. The clinical improvement was most noteworthy in a small group of infants suffering from convulsions. Where combined treatment was employed the resulting benefit seemed to be even greater, and the average duration of the paroxysmal stage was reduced, autogenous vaccines were more efficacious than stock vaccines. The mortality as compared with untreated cases was small: five children died, but in only two cases could death be attributed to whooping cough. No adverse symptoms of any kind followed the treatment, and there was a rapid shrinkage of the swollen lymph nodes, accompanied by a definite fall in the total number of the lymphocytes and in their relative percentage. This was most noticeable in the older children. It has long been suspected that the swelling of the lymph nodes is directly responsible for the paroxysmal cough, and the present authors agree that this is probably correct. The diagnostic value of the lymphocytosis is stressed, it was found in 88 per cent of the cases during the infectious catarrhal stage. The authors believe that early diagnosis is now possible in most cases by a combination of bacteriological, radiological, and haematological examinations, associated with a careful study of the history. They suggest that quarantine can be shortened to four weeks, during which period isolation would be practicable. Prophylactic vaccination is also recommended, it is thought that the immunity so obtained endures for about one year, and the treatment should therefore be repeated annually for three or four years to cover the period of greatest liability to infection. By joint action between private practitioners, hospitals, laboratories, and local boards of health a specific preventive and curative therapy could, they hold, be established, whereby the incidence, morbidity, and mortality of whooping cough might be as much lessened as has already come to pass in diphtheria and scarlet fever.

INSURANCE AGAINST DOCTORS' BILLS

A company called "Family Medical Services, Limited," with offices in Manchester, has arranged at Lloyd's a doctors' bills policy, with the object of providing first-class medical services for the middle and professional classes. The prospectus of this "Anchor" policy, of which we have been favoured with a copy, is not compiled in very lucid language. It would seem, however, that in applying for a policy all members of a family who reside at home and are eligible must be offered for insurance. The family is therefore the unit. Eligibility appears to consist in not being "on the panel" (that is, we presume, not an insured person under the National Insurance Acts), in being between the age of 12 and the age of 45 in men and 40 in women, and in being able to submit a satisfactory proposal, though no preliminary medical examination is required. But children between the ages of 2 and 12 years, and adults up to the age of 50, are accepted with a loading. If the proposal is accepted insurance may be effected under Table "A" or Table "B." In the first table insurance applies only to general practitioners' fees, under three classes according to the fee of the doctor, whether 7s 6d, 10s 6d, or £1 1s a visit. Under this policy the insured pays as premium 15s, £1, or £2 per person (eligible person, presumably). Of his total doctor's bills for each year of insurance the insured himself will pay, according to the visiting fee of his doctor, the first £2 10s, £4, or £8, plus 15s, 20s, or 40s for every

person over the number of two. Under Table "B" a premium per person additional to the premiums under Table "A" insures a proportion of the costs of operations and consultations. The additional benefits fall under four schemes, and in each scheme there is a limit to the amount payable per annum per person. There is much that is interesting in my attempt to help the middle classes to insure against the anxieties of heavy expense in illness, anxieties which were emphasized by Lord Dawson of Penn in an address on health insurance delivered not long ago before the Insurance Institute of London. But from the brief outline we have given of the Anchor Policy of the Family Medical Services, Limited, it will be seen that the matter is beset with many difficulties. The complications of the policy are increased by the express exclusion of venereal disease, alcoholism and its results, neurasthenia, childbirth, "change of life," any disease not common to both sexes, and accidents resulting from certain occupations and amusements or from civil commotion and war. It must be remembered also that the policy is an annual and not a permanent contract, so that medical fees for a chronic illness of more than a year's duration are not likely to be covered. While, therefore, we shall watch with interest this early and ingenious experiment in middle-class medical insurance, we are by no means certain that it is possible to be sanguine as to the results. The honorary advisory council of the Family Medical Services includes three leading members of the medical profession in Manchester—Sir William Milligan, Professor George R Murray, and Dr T A Goodfellow.

ASPHYXIATION AT GENEVA

The Health Organization of the League of Nations (writes our correspondent from Geneva, whose further report appears at page 578), extends its operations from China to Peru—it all events from the epidemiological service at Singapore to the collection of medical statistics in Latin America. But the course of the present Assembly at Geneva shows that it might very well direct its energies to its own household. Parliaments notoriously are stuffy places, which is the reason, perhaps, why political life is so often uninspired but something better might have been expected from the "Parliament of Man." The atmosphere at meetings of the League of Nations, both of the Assembly and of its six statutory Commissions, is almost insufferable. The Assembly meets in a public hall in Geneva, not so large as the Great Hall in the new House of the British Medical Association, and, of course, not to be compared with it in regard to modern and hygienic methods of construction. A glass roof adds to the general discomfort of the close days of September. Here the delegations of fifty-four countries have to be seated, each with its separate desk, and behind each its retinue of secretaries and technical experts. The galleries are allotted to the journalists and to as many of the public as can be crowded in. The accommodation is entirely insufficient, and for some time the League has been considering the building of a hall of its own—so far without any tangible result. The rosters of the present hall are faulty, its ventilation is bad, and the general crowding and jostling is a scandal worthy of the attention of that committee of the League which is charged with social and humanitarian affairs. But, ill housed as the Assembly is, the Commissions are worse off. The Commissions hold their meetings at the Palais des Nations, the home of the secretariat, where four large salons are available. Each of these salons has a vast window space overlooking the lake. The beauty of the outside view contrasts strangely with the discomfort within. The windows are apparently not made to open or, if they are, there is an unwritten law that they shall not be opened.

If a current of air stultifies the assembled delegates one may be sure that some enterprising Anglo-Saxon has discovered a window which gives upon the outer world, and equally sure that some less stealthy Latin will soon close it. In each of these salons also accommodation has to be found for the delegates of fifty-four nations, for their secretaries, for a small army of officials, for journalists, and for an eager public, very largely Americans, who show a zest for the League very unlike the attitude of their Government towards Geneva. Add to this that almost every delegate smokes incessantly, and the atmosphere at the end of a session, which may last for four hours, must be breathed to be understood. It is such a call to mind a tragic event in the history of Calcutta under the Viceroy of Bengal. Had some of the sessions been prolonged for another hour the wisdom of fifty-four nations might have perished from asphyxia.

AUXILIARY HOSPITALS

By an auxiliary hospital is meant a recovery home, something between a general hospital and a convalescent home, for patients who need not be kept in a hospital and are yet not sufficiently well to go to their own homes or to a convalescent home. A minor instance, entitled *The Auxiliary Hospital*, has been prepared by Dr J N Kay Menzie, director of hospital and medical services to the Joint Council of the Order of St John of Jerusalem and the British Red Cross Society, and Miss R H P Oide, B A, in which the purpose and cost of such hospitals are discussed. It is recommended that they should be situated in the country or at the seaside, and it is stated that they cost less in buildings, staff, equipment, and in maintenance than the parent hospital, although they are more costly in all these respects than what are commonly called convalescent homes. One of the largest of the Voluntary Hospital Committees in the country has examined this matter, and its conclusion is that "There may be a saving in capital expenditure and in some items of maintenance, but on the other hand there will be some extra cost of separate administration and of transport. The advantage of a recovery branch, as compared with extension of the hospital site, lies, therefore, solely in the benefit to the individual patient, not in any increase in the number treated for the same sum of money." Dr Menzie examines this statement in detail, and gives figures to show that where such an arrangement has been established "the combined cost per occupied bed at this hospital and its home of recovery is nearly £3 a year lower than at the parent hospital itself." In other hospitals it was evident that the long stay patients were returned because there was no accommodation available to which they could be sent, and for no other reason. It is hardly possible to imagine a more uneconomical use of parent hospital beds. The report concludes that "it can never be an economic proposition to add beds to the parent hospital and utilize them for the retention of patients a moment longer than is absolutely necessary. And we are of opinion that this is the true test of whether, in any given locality, extension should be by way of recovery branches or by way of beds at the parent hospital." The address of the Joint Council is 19, Berkeley Street, W 1.

EFFECT OF HEPATIC EXTRACT ON HIGH BLOOD PRESSURE

DURING recent years attention has been directed to the action of the various guanidine derivatives in raising the blood pressure, and more lately to certain tissue extracts which lower the pressure. In the biochemical laboratory and the physiology department of the University of

Western Ontario researchers have been in progress to determine the specific nature of the depressor principle in hepatic extracts, and Drs A A James, N B Lughton, and A Bruce Macallum now report in *Nature* (August 8th, p 208) that this principle is non-protein in nature and is found in the albumin fraction in association with a pressor principle. They add that the depressor principle is soluble in water and water-alcohol mixtures up to 80 per cent, is precipitated from aqueous solutions by phospho-tungstic acid together with the drummo acid fraction, and that the material recovered in aqueous solution can be further purified by extraction with ether. The physiological effect of hepatic extracts has been studied by these authors, and also by Dr R H Major of Kansas, who contributes to the *Journal of the American Medical Association* (July 25th, p 251) an account of its use in dogs and forty-two hospital patients. He reports that in subjects with normal blood pressures, tested as controls, the injection of a therapeutic dose was without effect, but that when the blood pressure was previously raised by the administration of guanidine derivatives, or in cases of arterial hypertension, a prompt though gradual fall of blood pressure resulted. The younger patients who gave no evidence of renal drainage or of arterio-sclerosis responded best, but some patients with obvious renal deficiency and definite general arterio-sclerosis were much benefited. Out-patients who were pursuing their usual occupations while under treatment were found to react equally with those who were inmates in hospital. Dr Major found that the fall in blood pressure was as a rule unaccompanied by symptoms, there was rarely some slight dizziness. In some cases the lowering of pressure persisted for only a few hours, in others it lasted for one or more days. Six patients proved quite refractory to the treatment, one of these died, and the necropsy revealed a most intense arterio-sclerosis of the splachnics. Dr Major concludes with the caution that the therapeutic value of these preparations cannot yet be assumed, but that further research should reveal whether their efficiency is limited to the benign group of cases which respond to drug treatment, or is capable of extension to the more malignant degrees of hypertension.

THE SOOTHING CIGARETTE

SCIENCE, unlike proverbial law, has never been unmindful of the smaller things of life, and it has now turned to study that placid contentment or even cheerfulness which graces the countenance of the tobacco user, often to the exasperation of those who neither smoke nor chew. Disregarding such niceties as the effect of nicotine on cats, so delicately dismissed by Cuvier, and passing over, with some reluctance perhaps, those earlier investigators who believe they have detected a lower standard of mental efficiency in tobacco devotees as compared with others, W L Mendenhall has contributed to the *American Journal of Physiology* (May, 1925) a report of experimental work designed to establish finally whether tobacco is to be classed as a boon or a bane. Only cigarette smokers are considered in this report, but the author indicates that the study of cigar and pipe smoking is being taken up as a separate problem, whether this distinction is due to obvious mental differences between the three classes of smokers or to profound variations in the composition of the grades of tobacco concerned, is not disclosed. The procedure adopted was, briefly, that the threshold of sensation to electrical stimuli was first estimated and checked accurately, the subject of inquiry then smoked two cigarettes in a well ventilated room (whether he or she inhaled the smoke is not stated), and the sensory threshold was redetermined. About 750 observations were

made but, strange to say, difficulty was experienced in obtaining a large number of subjects, the lure of two cigarettes (of a popular brand) or the appeal of science proving apparently inadequate to college students of both sexes, smokers and non smokers. It was found—whether as a surprise or not is undisclosed—that smoking has an effect similar to that of resting, and more particularly in restoring the human organism to the normal state. Thus, when the sensory mechanism was depressed smoking stimulated, but when the mechanism was hyperexcitable the effects were soothing or depressing. The depressing effect was more marked with tobaccos containing nicotine, when cubeb cigarettes were used stimulation resulted generally, whatever the state of the sensory threshold. No differences were observed in these respects between habitual smokers and non-smokers, but the one instance of maximum stimulation, and the single occasion of maximum depression, occurred in a non-smoker. This makes it hard to draw a moral. Commenting on his results Mendenhall finds himself able to explain the calming influence of smoking on a nervous, high-strung, irritable person and its power to relieve the mental ennui of brain workers. It would appear that tobacco smoking furours the maintenance of, or return to, a normal frame of mind. But into the vast speculative field thus opened up the author, perhaps wisely, does not venture to step. He does, however, go so far as to imply that this finding casts light on “a matter of common observation and experience, that smokers in whom the habit is undoubtedly established, and who are deprived of their smoke, show unquestionable signs of hyper-irritability of the central nervous system, and that these signs disappear both objectively and subjectively when smoking is indulged in.” This might have been put more tersely, perhaps.

IMPERIAL SOCIAL HYGIENE CONGRESS

THE Imperial Social Hygiene Congress organized by the British Social Hygiene Council (formerly the National Council for Combating Venereal Diseases) will be held at the British Empire Exhibition at Wembley from October 5th to 7th, under the presidency of Sir Auckland Geddes, GCMG, MD. The main points to be discussed are the imperial aspect of social hygiene, which will be introduced by Mr L S Amery, Secretary of State for the Colonies, reports on the administrative and naval position with regard to venereal diseases within the empire, methods of health propaganda in Europe and the Far East, the consideration of the problem of venereal disease with relation to race and climate, the diagnosis and the treatment of gonorrhoea in the male, a review of the position with regard to venereal disease in Great Britain and the self-governing Dominions, social hygiene in relation to the mercantile marine, the need of welfare work for merchant seamen, arrangements in the Australian Commonwealth for the mercantile marine, venereal disease and immigration, the diagnosis and treatment of syphilis, the problem of venereal diseases in India, syphilis and endemic disease in India, survey of the position in the various provinces, congenital syphilis in India, community social service in combating venereal diseases, the problem of venereal diseases in protectorates and mandated areas, and the selection of propaganda films. Further information may be obtained from the Secretary of the British Social Hygiene Council, Cartet Street, Westminster, S W 1.

THE KING has been graciously pleased to grant a Royal Charter to the Medico-Psychological Association of Great Britain and Ireland, which will henceforth be known as the ‘Royal Medico-Psychological Association of Great Britain and Ireland.’

INTERNATIONAL HEALTH.

WORK OF THE ASSEMBLY AT GENEVA

[FROM OUR CORRESPONDENT]

THE Health Organization of the League of Nations will be entrusted with many new tasks if the various proposals now before the Assembly at Geneva take practical shape. The Cuban delegation proposes interchange visits of the technical staffs of the institutes of public health in the countries of Latin America, the Italian delegation wants an inquiry concerning trachoma to be set on foot, and the Pan American suggests the dispatch of a medical statistical expert to certain countries with a view to comparing health statistics. The Czechoslovakian delegation has a more ambitious programme—it asks the League to undertake a comparative investigation of the health administrations of the various countries, "with a view to the economic, rational, and effective organization of such services, including those of national health insurance", also the drawing up of an international scheme for collecting information with regard to diseases treated in hospitals in order to establish statistics of morbidity and, finally, it asks for an investigation of the possibilities of achieving a unification of pharmacopoeias.

This is not all. The French delegation desires the establishment on the West Coast of Africa of a sanitary and epidemiological bureau. The representative of the Serbs, Croats, and Slovenes moves for an investigation of methods to be recommended for adoption by Governments for regulating, in the interests of public health, the manufacture of and trade in, foodstuffs. Then there is Venezuela which asks for the establishment of national health offices to serve also as liaison offices between the administrations of the various Governments and the Health Organization of the League.

All these proposals have been referred for technical consideration to the Health Committee with the proviso—rather a devastating one—that no additional expenditure must be undertaken over and above the present budget. At the meeting of the second committee of the Assembly, which is concerned with technical organizations, several delegates protested against this restriction, arguing that the efficiency of the Health Organization should not be allowed to suffer on the ground of economy, and that if no new expenditure is to be incurred on health activities the same denying ordinance should be applied to the other work of the League.

Epidemiological Intelligence Services

A report on the general work of the Health Organization was made to the Second Committee on September 16th by M. Oscar Velghe, secretary to the Belgian Ministry of the Interior and of Health. He spoke first on the epidemiological intelligence service. The Governments of several countries on the Mediterranean and Black Sea have decided to notify Geneva by wireless of the appearance of plague or cholera. The proposed epidemiological intelligence bureau has been set up at Singapore, thanks to the generosity of the Rockefeller Foundation, and has been at work since April last. It is now in communication with the principal ports of that part of the world, including those of Australia and East Africa. It co-ordinates the information received and transmits it weekly by telegraph to the interested health services in the Far East.

M. Velghe went on to say that the Health Committee of the League has appointed a section of experts to agree upon a standard definition of stillbirth in order that it may be possible better to judge of the efficacy of the measures taken to reduce infant mortality. This section has arrived at certain conclusions, which have been forwarded to the various Governments. Another body of experts has been appointed to study the tabulation of the causes of death. Since the last Assembly six Governments have sent in their replies regarding the sero-diagnosis of syphilis. It appears

from these replies that the system of notation which is advocated for use in indicating the results of the sero-reaction has been officially adopted in several of the countries. The investigations concerning serums in respect of which standardization is possible are well advanced, and some specific resolutions may be arrived at within a few months, and will be submitted for ratification to the various Governments.

Investigations on Cancer and on Malaria

From inquiries undertaken by the Cancer Commission of the League (M. Velghe continued) the supposition that there is a considerable difference between England, Italy, and the Netherlands as regards mortality from cancer of the breast and uterus has been confirmed. Investigation of the factors which may explain the difference are now in progress, and are likely to lead to interesting conclusions. With regard to the Malaria Commission, the results obtained during the recent tour of investigation have led the majority of the members to conclude that, valuable as is the quinine treatment, the most effective weapon against this disease consists in improved methods for the destruction of larvae and mosquitos. At the invitation of the Spanish Government the Commission has lately visited certain malarial regions in Spain. The French Government has asked the Commission to conduct an investigation in Corsica, and the British Government has also requested an investigation in its territory. As existing supplies of quinine are not wholly adequate the Commission has decided to arrange for clinical tests using cinchonine, a secondary alkaloid of cinchona, and the entire extract of that substance, so that their action may be compared with that of quinine. The Commission hopes to reach a decision on this point next year. The Union of Socialist Soviet Republics has recently solicited the co-operation of the Health Organization in investigating the causes of the persistence of endemic plague in certain parts of Eastern Siberia, bordering upon Manchuria.

Exchange Visits

The exchange visits of public health officials have proceeded. Certain exchanges of specialist officers—one such class being factory inspectors—have also been arranged. As it is difficult for doctors in the British Dominion to take part in these collective journeys, medical expert from Australia and New Zealand and from Canada have been charged with individual missions of investigation in Europe. The Canadian delegate made a thorough investigation of the methods in use in different European countries for combating tuberculosis. On this subject of tuberculosis investigations are now proceeding on the decline of mortality from this disease in the various countries, and the effect of industrial labour, of housing, and food supply especially milk, upon the frequency with which tuberculosis occurs. M. Velghe deplored that lack of funds had prevented the Health Organization from making a study of the problem of physical education and the means of its general extension on rational principles, as requested by the last Assembly.

Appreciation of the League's Work

Following upon M. Velghe's statement to the Second Committee, the delegates from a dozen countries spoke in warm approval of the work of the Health Organization. These included Mr. A. M. Samuel, M.P. (Great Britain), the Hon. George Swinburne (Australia), and Sir A. A. Chatterjee (India). The only word of criticism was with regard to the request from Soviet Russia, the Polish delegate, M. de Vasconcellos, remarking that the Soviet Republic had taken an antagonistic attitude to the League, and he very much doubted whether a mission of health would soften its heart.

A recommendation was passed, inviting the Assembly (which has still to receive the report) to record its satisfaction that Governments were more and more disposed to collaborate with the Health Organization in matters concerning the prevention of communicable diseases and the improvement of health conditions.

A CHINESE MALARIA EPIDEMIC

A SERIOUS epidemic of malaria in South China in 1923, the outcome of the civil war, is reported by Dr R Boeckh¹ of the Basle Mission, senior physician to the Mission Hospital at Hoyun, near Canton. He says that in travelling up the East River from the Canton delta, just before reaching Hoyun a great new graveyard is passed, in which, in three weeks of October, 1923, 700 were buried, dead of malignant tertian malaria, which suddenly burst upon a community accustomed indeed to benign tertian, but with no immunity against the locally unusual malignant form. Europe, he adds, learned much of epidemics in the great war, the old civilization of China, too, enduring from unwise doctrines and robber brigades many trials since the revolution of 1911. It has experienced war-famine, plague, cholera, and malignant malaria, besides which the country folk were formerly free from syphilis, which now causes three-quarters of the diseases they complain of. The mercenaries, levied from all over China to fight in these wars or looting expeditions, picked up diseases everywhere and carried them round, and when they go back infected to their homes China in the after-years finds fun to become the most disease-infested of all lands. For example, plague has become endemic in the East River valley, where it was unknown before 1917.

In 1923 Sun Yat-Sen made a move against Chen from Canton up the East River, starting from the area of endemic malignant malaria, against which the natives of the delta had a certain immunity, though his troops had none, many of them being North Chinese with no experience of malaria nor even of tropical heat. The summer of 1923 was very wet, with quite unusual inundations in the delta and in the valley where the troops lay. In consequence the September swarms of anopheles came out in myriads. The South Chinese knew their risks and sheltered in the houses of the country folk, while the inexperienced northerners became heavily infected. They had no quinine or mosquito protection. As soon as the floods had gone down Sun marched up the right bank of the East River, reaching in a few days his objective, Hoyun. Poor food and overexertion in the heat had on the way exhausted his men, the river crossing was opposed, and their malarial infection began to manifest itself. The people of Hoyun who lived outside the walled city fled in thousands to the walled Mission Station, and Sun's troops flooded the Mission Hospital (sixty beds), where three or four hundred were accommodated daily, and 1,400 malarial cases, nearly all malignant, in three weeks. In October Sun's force was defeated and in flight, its route bordered by hundreds of dead and dying, overcome by hunger and malaria. The people of the Hoyun suburbs now returned to their houses, and in ten days Dr Boeckh was called to deal with their new malarial epidemic, contracted from Sun's army. It attacked almost exclusively the people in the open suburbs, not those in the walled city. It showed itself first along the right bank, the left was subsequently infected by human carriers, at crossings, especially where there were markets.

At this season the usual malaria was benign tertian, everyone was prepared for that. But this was different, much more severe, and they called it "the Spanish disease," as it reminded them so much of the so-called Spanish influenza of 1918-19. It ceased in the cold weather, but how heavy had been the cost! Of 10,000 dwellers in the environs of Hoyun, 700 (besides children) had been reported dead, whole families had been wiped out, others had lost nearly all their men. As resistance was low, the malarial infection had been all the more virulent, and the immunity acquired in wars against the benign tertian failed altogether against the malignant form. Sun's soldiers were very heavily infected (eight to ten crescents in a single microscopical field, and they appeared a very few hours after onset), blood destruction was very rapid, and early anaemiasis marked. The fever curve was quite irregular, sometimes resembling that of typhoid, and of no prognostic value, men died at 102° F, and lived at 106°. The cases were as various as in influenza epidemics: intestinal, gastric, cerebral, and pulmonary forms were seen, but always with malignant parasites. Quinine (15 to 45 grains daily) cured the most unlikely cases—even three of eight resembling

amoebic dysentery, though no amoebae were present. Many bronchitis cases were seen. Spleens were large, tender, and hard, even in early cases (splenitis was excluded), and decreased quickly in convalescence. Nervous symptoms were more frequent than usual, those patients with coma were mostly syphilitics. Quinine with salvarsan was the best treatment for them.

As Dr Boeckh points out, this is an unusual history of an epidemic of malignant tertian spreading in special circumstances into a region hitherto unattacked. It is fortunate a careful observer was there to report it so exactly.

If the epidemiologically most important considerations are put together shortly it may be said that in the endemic area of malignant tertian, in the Canton delta, anopheles, thanks to the inundations, came out in unusual numbers that September, and in the epidemic area got themselves infected, and after a fortnight began to infect the troops heavily and widely. These soldiers were inexperienced in malaria, quite unprotected, and unable to look after themselves. With their malaria still undeveloped, they tickled up the East River, in heat and discomfort from bad roads and heavy loads, and when, with the onset of the fever, a fortnight later, their blood became infective, they were at Hoyun, in a region which so far only knew the benign tertian. Into this district, with a climate, it may be supposed, ordinarily only suited to the development of *Plasmodium vivax*, they in the warm season brought a mass infection for the mosquitos of *P. falciparum*, which in that hot time in 1923 was able to develop. After a fortnight the local mosquitos were infecting the local people, the original carriers, Sun's troops, were then driven out ten days later the new infections began to develop, and the epidemic of locally arising malignant malaria, novel to the district, appeared. Quite an interesting story—all the more, as Dr Boeckh says, because so little is known of the history of the development of malaria in China.

The course of events may be briefly reconstructed thus. In the first week of September a young female anopheles at Canton bit a Cantonese who had had malignant malaria, and had not been cured. In a fortnight it, now infectious, infected one of Sun's North Chinese, who, marching up the East River, became very exhausted, so the parasites grew as they liked in his blood. At the end of September he fell sick at Hoyun, where a local anopheles bit him and became heavily infected. In a fortnight more it spread the disease to a native Hoyunese, who in another fortnight, at the end of October, went down with a malignant tertian fever his friends could not understand, having never seen a malarial fever without a remission every other day.

England and Wales.

METROPOLITAN ASYLUMS BOARD

THE widespread activities and the excellent services of the Metropolitan Asylums Board are known to all. The annual report issued by the Board never fails to provide a comprehensive survey of the manifold problems of public health which are being assiduously studied and determinedly attacked.

Diphtheria

In its report for 1924-25 the Board, in reviewing the incidence of the various infectious diseases, directs special attention to the increase of diphtheria during the past fifteen years. As the incidence of diphtheria on children under 10 years of age is about two-thirds of the total, the likelihood of a child under that age becoming infected with the disease is now approximately twice as great as it was in the period immediately prior to 1911. The Board considers these figures a powerful argument for the adoption of some form of immunization in an attempt to stamp out the disease.

The recent figures for New York City show a marked decline in the incidence of diphtheria, and it seems reasonable to conclude that this has been due, in part at least, to the immunization measures adopted there during the past few years, over 500,000 school children in that city having been tested, and about 125,000 of these found susceptible, having been immunized against diphtheria.

¹ Arch. f. Schiff- und Tropen Hygiene vol. 29, Jah. 1925 p. 305

The application of the Schick test is but a trivial matter involving neither pain nor subsequent discomfort, and having regard to the fact that it is possible to ascertain, with almost complete certainty, whether or not a person is susceptible to diphtheria, the Board now requires every new member of the nursing staff to be tested on joining for duty in any of its fever hospitals, and if found to be susceptible to diphtheria to be given the option of being immunized against the disease.

One of the Board's officers, Dr Frederick H Thomson, medical superintendent of the North Eastern Hospital, has urged the revision of the methods of bacteriological culture before discharging diphtheria convalescents. Dr Thomson found that, by a more intensive system of cultures, in which six consecutive negative cultures from throat and nose spread over a period of three weeks were required, a certain number of carriers who continued to show virulent diphtheria bacilli had been found. In this investigation Dr Thomson had the assistance of Dr W Muir, Assistant Director of Pathological Services, and of Mr Humphrey Munier, F R C S, for the performance of minor operations on the throat and nasal passages, as the only remedy in certain cases is such an operation.

Encephalitis Lethargica

It was indicated in the last report that the year 1924 was likely to be marked by heavy incidence of encephalitis lethargica, and this surmise has unfortunately been fully borne out. The total number of cases notified during 1924 was 611, a figure which approached a level three times as high as the highest previously recorded (233 in 1921). Apart from its intrinsic seriousness and the difficulties in the way of effective treatment, the distressing psychological changes which sometimes follow in its train render it one of grave sociological implication. The need for providing institutional treatment for juvenile cases is acutely realized, and the Board, regarding itself as the most suitable authority to move in the matter, has informed the Ministry of Health of its willingness to undertake such duties in the matter as might be thought necessary.

Scarlatinal Otitis

With a view of diminishing the number of cases of otorrhoea in its fever hospitals the Board, some years ago, appointed Mr T B Layton F R C S, as otologist, to enable a thorough investigation of this problem to be made. As a result of his extensive study of this question, Mr Layton formulated a number of conclusions, which are embodied in an exhaustive report made by him to the Board. Mr Layton gives the following list of instructions for the treatment of ear disease in scarlet fever:

(a) By incision of the drum head in every case in which it can be found to be bulged before it ruptures.

(b) By the cleaning of the meatus and the instillation of antiseptic hygroscopic drops when otorrhoea has occurred (Mr Layton informs us that the drops he uses contain glycerine of earbolite acid one part rectified spirit one part and glycerine two parts. He published a detailed account of the treatment in the *British Journal of Children's Diseases*, vol xx p 65).

(c) By considering the question of performing an operation upon adenoids when there has been ear discharge for twenty one days in simple scarlet fever or longer in septic scarlet or mixed infection.

(d) By the performance of a Wilde's incision as soon as a retroauricular swelling or a drena appears when this is not due to cervical adenitis.

(e) By opening the mastoid in such acute conditions of the bone as do not seem amenable to treatment by Wilde's incision.

(f) By performing an operation on the mastoid in those cases where a Wilde's incision has been done and in which the general symptoms do not subside or recur or the wound does not heal or the ear discharge continues.

(g) By performing an operation on the mastoid in cases where the ear discharge threatens to become chronically established and in which evidence of changes in the bone of the mastoid can be proved by radiography or otherwise.

(h) By the treatment by heliotherapy of such cases as are tending to develop chronic otorrhoea, whether these have had any operative treatment or not and whether they have suffered from simple scarlet from septic scarlet fever or from a mixed infection.

Mr Layton's recommendations were carefully considered by the Board, who were advised by Dr Doord Caiger, the chief medical officer of the Board's infectious hospitals service, after consultation with three of the medical superintendents. With one exception the recommendations by Mr Layton met with unanimous approval. In regard, however, to the advisability of incising the drum head in every case where it is found bulged, the Board's advisers felt considerable doubt. They contend that the opportunity of performing anticipatory puncture is often precluded because the occurrence of a discharge is the first indication that the ear is affected, and that the procedure is practicable on only a small percentage of cases.

Research

In October, 1922, the Board appointed a Scientific Advisory Committee to advise on the organization of pathological and research work and on kindred subjects. Acting on the recommendation of this committee, the Board recently established the post of Director of Research and Pathological Services, and appointed as its first director Dr J B McCutney. His duties will comprise those of general administration of the Board's laboratories and the carrying out of research work into the causation of various diseases. It is not considered that the administrative duties will interfere in any way with those of research. Dr McCutney contributes to this report an article on attempts to demonstrate a filterable virus as the etiological agent of a scarlet fever. The virus isolated was shown ultimately to have no otological relationship with scarlet fever, and is probably an unknown rabbit virus, but the experiments are of interest, they demonstrate the great difficulties attendant on the search for the etiological agents of disease, and emphasize the absolute need for controlling fully all experimental work.

The provision by the Board for research into the causes and prevention of mental deficiency has been considerably enlarged by the establishment of a laboratory at the Fountain Mental Hospital. The supervision of this work will be undertaken by Dr L B Sherlock, chief medical officer of the Mental Hospitals Service. This service also to have the advantage of the services of a consultant neurologist and a consulting surgeon, the first occupants of these posts being Dr Kinner Wilson and Mr Price Thomas, F R C S.

Post-Graduate Instruction in Manchester

The post-graduate teaching at the Manchester Royal Infirmary during the coming year will follow the lines previously established. On Tuesday afternoons lectures will be given in turn by the acting honorary staff and on Friday lectures on recent clinical and scientific work will be delivered, partly by the honorary advisory staff, which includes university professors who are not on the clinical staff at the hospital but who teach scientific subjects bordering on medicine. Professor W L Biagg will speak on the nature of rays, and Professor Stifford will continue the role lectures of the past years on the motor and sensory systems by giving two on the sympathetic nervous system. The appointment of such an honorary advisory staff has been of great assistance to the hospital, it was one of the numerous wise steps taken by the infirmary board during recent years, and is a sign of the growing intimacy between the university and the infirmary, as well as of the smooth working of the Manchester medical school. The lectures are open to all medical practitioners and to students interested in the subjects. A syllabus of lecture has been issued and an advertisement is inserted in our present issue. Dr E Bosdin Leech is the honorary secretary for these courses.

Sale of Food and Drugs

The results of administration of the Sale of Food and Drugs Act for the past year are summarized in a publication of the Ministry of Health containing extracts from the annual report of the Ministry relating to the subject,

together with an abstract of the reports of public analysts. We note that the total number of samples of all kinds examined was 118,000, being 3,154 more than in the previous year. The proportion reported as adulterated or not up to the standard was 5.9 per cent, it was 6.1 per cent in 1923 and 6.2 per cent in 1922. Milk continues to furnish the chief subject of interest. Out of 62,133 samples analysed 47,773, or 77 per cent, were not reported genuine. Of these 45 contained preservative, but only one was preserved with formaldehyde, the vendor in that case suffering the exemplary penalty of a fine of £30. Although the number of glaring offences is quite small the need of stringent control is exemplified by the discovery of a case of systematic addition of water to milk in adjusted quantities so as carefully to avoid trespass on the standard which would have been detectable by analysis, and also by the increased proportion of adulterated samples found in sundry deliveries, in one county it was almost double the plain average for the year. The powers conferred by the Milk and Dairies (Amendment) Act, 1922, have been used to remove the names of two vendors, convicted for adulteration, from the register of purveyors, thus preventing them from trading in milk. There is a growing tendency for the names of articles of a certain class to lose their meaning. One analyst remarks that the term "ice cream" may be used to describe any frozen preparation from sweetened water to sweetened cream. Another analyst states that lemon cheese should be made from butter, sugar, eggs, and lemons, whereas in fact little or none of these ingredients is used in its production. "Custard powder" is applied to a coloured and flavoured maize flour. The trivial offences of this kind add difficulties to the correction of the more serious abuses of description. An editorial article appeared lately in one of the London daily papers dealing lightly in satirical vein with the comments by an analyst on lemon cheese, but the application of the term "paregoric" to a liquid devoid of opium shows the length to which such abuse may go. Since paregoric contains a scheduled poison and thus may only be sold by registered pharmacists, certain unregistered drug store proprietors have sought to meet the request of their customers by supplying an imitative preparation containing no opium. Of 5,901 samples of drugs examined, 315 were reported not genuine. The principal defects were found among borax, sweet spirit of nitric, and medicines dispensed from prescriptions. Cream of tartar as an ingredient of baking powder has been generally replaced by acid calcium phosphate, and thus another confusion of names has grown out of the substitution. But while the substitution in baking powder may be legitimate, cream of tartar has distinct uses as a drug, and the confusion of nomenclature would be unfortunate if not checked. We note, however, that one sample only, out of 478 examined, was reported to contain phosphate, and that only four samples were certified to contain lead or arsenic in excess of the limit allowed.

TREATMENT OF TUBERCULOSIS

The Ministry of Health has issued a memorandum (37/T) concerning the annual reports to be furnished by the chief administrative tuberculosis officers of local authorities and the records to be kept by tuberculosis officers and medical officers of residential institutions approved by the Minister of Health for the treatment of tuberculosis. A covering letter (Circular 613) has been addressed to county councils, county borough councils, and tuberculosis joint committees in England and Wales, and another letter (Circular 613b) to the authorities of sanatoriums and other residential institutions approved for the treatment of tuberculosis. The memorandum has resulted from collaboration between the Tuberculosis Society, the Tuberculosis Section of the Society of Medical Officers of Health, and the Society of Medical Superintendents of Tuberculosis Institutions, the County Councils Association, the Association of Municipal Corporations, and the London County Council have also been consulted. An obligation is placed upon the chief administrative tuberculosis officer of each area and the medical officer of each approved residential institution to furnish to the Minister of Health certain statistical reports,

model forms of records are suggested, but these are not obligatory. More complete and systematic information will now be obtained than hitherto. The Minister also desires to receive annually general information about the working of local tuberculosis schemes, including accounts of any noteworthy developments or changes. Certain terms are defined with a view to stating the results of public medical treatment. Cases are to be described as "quiescent" in which no symptoms or signs of tuberculosis are present, except those compatible with a completely healed lesion. The term "arrested" is to be applied only to cases which have been quiescent for at least two years, but in non-pulmonary cases the term may be used as soon as there is reason to believe that the disease is unlikely to recur. It is added, however, that non-pulmonary cases should not be discharged as "cured" until three years have elapsed without there being any signs or symptoms of active disease. Cases in which the general health is fair and the symptoms of tuberculosis have materially diminished are to be termed "improved", and in all other patients who are alive the term suggested is "no material improvement". In order to obtain the statistical information each tuberculosis officer and the medical officer of every approved residential institution should keep a register containing information about all persons dealt with, whether coming for treatment, observation, or advice. It is added that all patients on a dispensary register should as far as possible be examined at least once a year by the tuberculosis officer, and their homes be visited periodically by the health visitor or dispensary nurse. Treatment at the dispensary—as distinct from diagnosis, consultation, and general supervision only—should, as a rule, be limited to patients whose continued treatment requires special knowledge or technical skill, or who cannot obtain other adequate medical attendance. It is further stated that patients whose treatment does not call for experience or skill beyond that ordinarily possessed by the general practitioner, and who are either insured persons or who can afford to pay for medical attendance, should not be encouraged to attend the dispensary for a routine treatment. On the other hand, a patient who only needs general supervision and no regular systematic treatment should not be referred to the general practitioner for treatment, and a form is provided for reporting such cases annually to the Ministry.

PREVALENCE OF SMALL-POX

In the first seventeen weeks of 1925 (as nearly as possible a third of the year) the total number of cases of small-pox notified in England and Wales was 2,393. The highest figure included in this total was 176 in the seventeenth week. Since that time there has been a steady drop in the notifications, the total for the second seventeen weeks having been 1,433, a diminution of 960. The figures for the last six weeks of the seventeen have been 65, 45, 63, 34, 50, and 37 respectively, whilst the next following week has had only 32. This fall in prevalence is very gratifying, and is apt to induce speculation as to whether the flood tide may not at last have been reached of the small-pox recrudescence which, starting from the extreme ebb of 1917, has steadily gathered force in the succeeding years. But it is much too soon to venture on prediction. In 1924 the total notifications were 3,784, and already, with one-third of the year to go, that figure has been passed in 1925. In the third quarter of 1924 the year's prevalence was at its minimum, there being only 643 notifications, as against 1,195 in the previous and 1,413 in the subsequent quarter. Indeed, the incidence of small-pox is usually lowest about this time of year, and it cannot be assumed that 1925 is any exception to the rule of seasonal prevalence. The northern parts of England continue, as hitherto, to be most affected by small-pox, Derbyshire, the North Riding of Yorkshire, the counties of Durham and Northumberland being all involved. Further south the county of Notts still reports cases, but the rest of England, including London, has had hardly any, and Scotland and Wales are in a similar happy position. Also, the disease continues to be of the same mild type as since the beginning of the present long-continued prevalence.

Scotland.

THE HEALTH OF GLASGOW IN 1924

The annual report of the medical officer of health for Glasgow has now been issued, and is packed full of information bearing on the physical welfare of the inhabitants. The author is Dr A S Macgregor, the period of office of Dr A K Chalmers having terminated at May 31st. The population at the middle of 1924 is estimated at 1,095,969, the estimate being based on a return of occupied houses. The institutional population was 30,104. The average density was 57 persons to the acre, and the number of inhabited houses 239,179, an increase of 1,447. Unoccupied houses numbered 449, that small figure being 124 more than in the previous year. The birth rate was 23.11, the death rate 15.39, and the infant death rate 119 per 1,000 births. The birth rate has declined steadily from 36.6 in 1871-80, and the death rate from 24.22 in 1881-90, to the rates given above for 1924. Owing to a lower estimate of population, the Registrar-General's rates are slightly higher than those of the medical officer, and, as in the past years, the report shows the Glasgow rates compared with those of the other three largest cities in Scotland, and the four largest in England. Next to Liverpool, Glasgow has the highest birth rate, and next to Dundee it has the highest death rate. The rate from infectious diseases in Glasgow was 1.71 in 1924 as against 1.46 in 1923, the excess being almost wholly due to whooping cough prevalence in the early spring, when pneumonia and influenza were also prevalent. Tuberculosis shows improvement.

Cancer has declined for the first time in a considerable number of years, the rate in 1924 being 1.16, against 1.19 in each of the two previous years. This improvement, it is remarked, may be a hopeful augury and reflect the results of early treatment. The cancer death rate in four residential wards of the city was from two to three times as high as in three typically antisocial wards. Deaths from rheumatism are considerably lower than in the two preceding years, and it is recorded that the deaths from alcoholism remain remarkably few, the rate per million having been 21 in 1921, and only 6 in 1923 and 7 in 1924. The death rate from nervous diseases as a group has, since the beginning of the present century, been remarkably uniform at from 1,600 to 1,700 per million. As in all the other cities with which comparison is made, the infant death rate has been higher in Glasgow in 1924 than in 1923. Of the four Scottish cities, Edinburgh has a much lower rate than the rest, while Glasgow comes out rather better than Dundee and Aberdeen. The infant mortality in the first month of life represents nearly one third of the total. Following the sections dealing with vital statistics, the report, which extends to 320 pages, proceeds to treat of all the other departments of health work undertaken by a great municipality—maternity and child welfare, infectious, respiratory, and venereal diseases, hospitals, offensive trades, port local authority work, housing the bacteriological laboratory (now much extended in accommodation and equipment), and general sanitation. Part II of the volume contains the annual reports of the hospitals and sanatoriums belonging to the corporation. Illustrations are given of the new buildings of Knightswood Hospital, the plan of a child welfare centre, and the extended laboratory of bacteriology.

NEW REGULATIONS REGARDING THE SALE OF MILK

The Scottish Board of Health has now issued to local authorities copies of the Milk and Dairies (Scotland) Order, 1925 and the Model Dairy By-laws. The Order prohibits the transfer of milk from one vessel to another in public place like railway stations, streets, etc., where it might become contaminated by dust. Milk in milk vessels must not be kept in a byre, kitchen, dwelling-room, or other place likely to cause contamination, nor in any place exposed to foul effluvia or impure air. After January 1st, 1927, the conveyance of milk in wooden vessels is prohibited, and all vessels used in transit must bear the owner's name and address. Carriers must take precautions to prevent milk vessels from being exposed to heat or to contamination, and after January 1st 1926 all vessels (except bottles) consigned for transit must be either sealed or locked. A part

of the Act deals with structural conditions in regard to cowsheds. These provisions are especially directed against conditions likely to favour the harbouring of infection, especially that of tuberculosis.

NEW PROFESSOR OF ANATOMY AT DUNDEE

The post rendered vacant by the retirement of Principal J Yule Mackay, M.D., from the Chair of Anatomy in University College, Dundee, was filled by the University Court of St Andrews University on September 15th by the election of Dr D R Dow. The new professor is a graduate of St Andrews University. Since 1913 he has been Lecturer on Regional Anatomy at University College and assistant successively to Professor Musgrave and Professor Waterston, the Bute Professors of Anatomy. He has carried on general practice at Crail, first in association with his father, the late Dr Dow of Crail, and, after the death of the latter, independently. Professor Dow is 37 years of age, and has contributed various articles on anatomical subjects to medical journals.

INCESSANT PRESCRIBING

In the report of the Executive Committee for the annual meeting of Insurance Committees to be held at Rothes at the end of this week it is stated that in the year 1924 there was an extraordinarily heavy claim upon the Drug Fund. The total expenditure for the year amounted to approximately £176,000, leaving a balance of £80,000 to be carried forward to 1925. The Executive Committee urges the necessity for vigilant scrutiny of Drug Fund expenditure, because, so far as information can be obtained, there appears to be no lessening in the present year. The Committee considers that extravagant prescribing, possibly unchecked for years, is to a large extent the cause of this high expenditure.

Correspondence.

THE DIVORCE OF SURGERY FROM MEDICINE

SIR,—It is wonderful how this story of the Council of Louis keeps cropping up. I should much like to find out who started the tale, and especially the phrase *Fœclesia abhorret a sanguine* as applied to it. Like Dr Cullen (*Journal*, September 12th, p. 494), I have carefully searched the Acts of the Council, and entirely agree with him.

A great authority, the late Edmund Bishop, in a private letter endorsed my view of the curious historical error in Sir Clifford Allbutt's book. In a paper on the Biber Surgeons (International Congress, 1913), and in my little treatise on *The Early History of Surgery in Great Britain* (1920), I pointed out that there is not a word in that Council about surgery, priests, or the shedding of blood, but merely an order against monks and regulars going out of their houses to study and make money in pharmacy, law, and medicine. This order has an interesting history, as Dr P Cyprien shows in his recent book on Salerno. He tells us that the early Benedictines, in the absence of secular teachers, started so many schools of medicine, and practised it so widely outside their convents that towards the year 1200 their medicine became a serious hindrance to their monastic work. Fortunately the new universities appeared at that time, and began to train lay physicians to take up the work. A whole series of Councils then forbade the monks to neglect their own duties for the practice of law, pharmacy, and medicine—for example, Rheims (1125), London (1138), the Lateran (1139), Montpellier (1162 and 1195), Paris (1212). Our Council of Louis thus took part with others in a needed reform. That, however, had nothing to do with the exclusion of the clergy from surgery. Indeed, they were not excluded by any rule till long after fashion and popular opinion had confined surgery to men of a low social rank. The separation of medicine from surgery arose, as Chauliac says, in the time of Albucares (? about 1050). This seems to have been partly due to Moslem feeling and partly to the aristocratic tendencies of the age, which despised manual labour and arts.

The first rule of the Church forbidding priests and deacons to practise surgery was a canon of the Lateran Council of 1216, confirmed as a decretal of Gregory IX (lib III, cap 9, tit 50) in the year 1234, or nearly two centuries later. This was followed by others, but they do not seem to have amounted to much, for exemptions were freely granted, as in the case of Chauliac himself, and in 1310 we find the Council of Bezeiers apparently ignoring the decrees, and ordering that priests and monks who practise surgery must have the bishop's licence. Surgery itself cannot feel slighted by the canon of 1216-34, for Honorius III, in 1216, ordered the secular clergy to abstain from physicians' work, because, he said, they should attend to their own studies.

As a matter of fact the wretched separation appeared chiefly where the evil influence of the University of Paris was great. There was very little of it in the South and in the early Italian universities. Even in England, as soon as university records appear, we find surgeons among the graduates—I am, etc.,

Clifton Bristol Sept 20th

GEORGE PARKER

COLLECTIVE INVESTIGATION OF RHEUMATOID ARTHRITIS AND ALLIED CONDITIONS

SIR,—I am surprised that Dr Logan's letter on the above subject (BRITISH MEDICAL JOURNAL, August 8th, p 271) has not provoked more correspondence. Few medical men of experience will quarrel with his opinion that "rheumatoid arthritis and allied conditions cause more human suffering and incapacity than that produced even by malignant growths."

Cancer with its almost inevitable "sentence of death," evokes a dramatic appeal to public sympathy. Rheumatoid arthritis presents no such immediate appeal, in one way, perhaps, the saddest part is that it does not kill. Its victims are hidden away in quiet places to suffer years of tortured crippledness. Its very chronicity tends to sink it to the position of an accepted fact, and there is no press agitation to beat up funds for its investigation.

In his opening paper on the subject at the recent Annual Meeting of the British Medical Association, Sir Humphry Rolleston gave a masterly summing up of the present state of our knowledge. There was a distinct note of encouragement, and I believe with Dr Logan that an investigation might well be undertaken "with rather more hope of beneficial results than in the case of cancer."

Where are the funds to come from to organize and maintain such a research? Possibly the friendly societies might do something to ease their present burden of £2,000,000 a year sick pay for rheumatic diseases. The equivalent of just one month's expenditure would put the thrug on a good basis, and would probably be a very sound investment. Again, the trade unions might devote a small fraction of their funds to this object, which would be likely to bring in more benefit than many of their present ways of dissipating their accumulations. Such a step would be a fitting complement to their present policy of establishing convalescent homes for their members—I am, etc.,

Cheltenham Spa Sept 21st

J S KILLETT SMITH

LATENT PERIPHERAL NEURITIS AND THE ANKLE-JERKS

SIR,—In the report in your issue of September 12th of the recent discussion on multiple neuritis held at Bath, I am glad to see that Dr Hurst insisted on the importance of latent—that is, symptomatic—neuritis.

As regards diagnosis, it is wise always to test and record the condition of the ankle-jerks—in particular amongst the tendon reflexes—before administering the drug, either in organic or inorganic form, and at weekly intervals during treatment. I have been struck by the fact that abolition of the ankle-jerks in arsenical and other forms of peripheral neuritis may be very temporary. In two cases seen recently the condition would have been missed but for routine periodic examination, for the neuritis was symptom-

less. Moreover, a careful examination disclosed no other evidence whatever of the condition.

A girl of 13, under treatment for chorea by my house physician was taking 30 minims of liquor arsenicallis each day. The dose had been increased gradually from 6 minims a day. On the third day (June 3rd) of the larger dose the ankle jerks previously healthy, were found to be abolished. The calf jerks were normal. The knee jerks were unaffected and there was neither motor nor sensory abnormality subjective or objective. The drug was omitted and five days later (June 8th) the ankle jerks were once again elicited. The observations were made by me. On June 1st and 2nd there was vomiting and on these two days only there was fever associated with tonsillitis. The vomiting, therefore may or may not have been due to the drug.

A boy, aged 6 under treatment recently for severe diabetes mellitus showed no evidence of peripheral neuritis. On the sixth day of treatment the knee and ankle jerks were all abolished and some of the muscles involved showed impaired faradic responses and polar changes. Ten days later the reflexes were again elicited.

In the treatment of syphilitic disease I have pushed organic arsenic until the ankle-jerks, previously healthy, have been abolished. The reflexes in all have at a later date been elicited normally. I am sure that the earliest and often the only sign of poisoning by arsenic may be bilateral abolition of the ankle jerks. It follows that in the case of a treated patient with nervous syphilis whose ankle jerks are absent we may be uncertain whether their absence is due to disease or treatment.

As regards symptomless neuritis from alcohol, I have found the ankle-jerks abolished, in the absence of any other detectable abnormality of the nervous system, in people who take spirits. I believe that alcohol may show its early action on the nervous system in this way only.

A woman of 26 under treatment at present for asthma and dyspepsia has been accustomed to take spirits in moderation in India for two years. She presents symptomless abolition of the ankle jerks. The knee jerks are healthy and the calves are not tender. Serum and cerebro spinal fluid are healthy and the nervous system otherwise appears to be quite normal. During three weeks, although the temperature has been persistently subnormal, her average pulse rate has been 95.

In several young persons of subnormal intellect I have failed to elicit the ankle-jerks, whereas all the remaining reflexes have been present—a solitary abnormality in what have appeared to be otherwise healthy physical states—I am, etc.,

HILDRED CARLILL,

Physician to Westminster Hospital and West End Hospital for Nervous Diseases
London W 1 Sept 17th

ACUTE THYROIDISM

SIR,—The report by Dr Clifford Nash (BRITISH MEDICAL JOURNAL, September 19th, p 519) of rigor and a rapid rise of body temperature accompanying the death of two patients with exophthalmic goitre is of considerable interest to me as I have observed the same phenomenon in rabbits fed with thyroid extract over a prolonged period. I have described in a paper, which will appear in the next number of the *Journal of Physiology*, that rabbits after prolonged thyroid feeding are in a condition in which sugar given intravenously or by mouth produces hyperglycaemia followed by severe hypoglycaemia, convulsions and death, rigor being immediate. The appearance of the hypoglycaemia, I now find, in experiments which are being carried out together with Dr J Hoet, is accompanied by a striking sudden rise of body temperature which may reach 108° F. The suggestion is forced on me at once that the rise of body temperature at the death of a patient suffering from exophthalmic goitre may similarly be accompanied by a fatal hypoglycaemia—I am, etc.,

POSTURE FOR BRONCHIAL AND TRACHEAL DRAINAGE

SIR—I am glad to see that Dr Neild calls attention to the value of bilateral drainage by posture in the BRITISH MEDICAL JOURNAL of September 19th (p 504). He produces the necessary downhill slope of the trachea and bronchi by a pile of firm pillows under the middle regions of the patient who lies in the lateral position. The mouth projects just beyond the edge of the bed. If necessary the foot of the bed is also lifted.

The question I wish to raise is whether it is not just as effective to drain the trachea by merely lifting the foot of the bed. If so, it is simpler, easier, and more comfortable, I would think except possibly when the diaphragm is paralysed.

The "death rattle"—so distressing to those who have to hear it for hours—may be taken as illustrative of cases requiring tracheal drainage. Here the liquid mucus merely surges noisily to and fro in the trachea, accumulating till perhaps it kills. The patient may be too comatose to cough, and his larynx will—for example in meningitis—be yawning open. This laryngeal sentinel—once so sensitive and alert—is no longer capable of co-operating in a cough or of preventing the aspiration of fluids from the mouth.

All one has to do is to prop the foot-end of the bed upon a chair, with a pile of large books about a foot high upon it. Turn the patient's mouth into a dependent position and place cotton-wool under it. In a few minutes the death rattle will cease and many diachms of horrible mucus will drain on to the cotton-wool, simply because the trachea now slopes gently downhill. The mucus still surges to and fro—slightly and silently—but its current now is pre-dominantly outwards instead of inwards. The amount of mucus in the first few minutes seems more than could come from the trachea alone—some must come from the lungs.

Now if it is adequate thus to drain the trachea, why complicate matters with piles of pillows to drain the bronchi? I fancy that expiration will empty them if the trachea is kept drained. The bronchioles are even more important, and Dr Neild cannot empty their ramifications by gravity alone.

I do not think that bronchiectasis needs constant postural drainage. Daily inversion will often cure an empyrable cavity. One lad I remember years ago produced pints of stinking pus for many weeks. By daily inversion he was quickly cured after drugs and surgery had failed and became a healthy insurance agent in later life. Raising the bed-root will relieve many troublesome coughs also.

Now that Dr Neild has so ably opened this subject, I hope others will write their experience of this simple, valuable, and too little used device—I am, etc.

Hull Sept 19th

FRANK C. FAY, M.D., F.R.C.P.

BACTERIAL VACCINES

SIR,—Having been abroad until recently, I have not had the opportunity of replying to certain comments made by Dr Mier Coplans on my observations regarding the antigenic value of different types of vaccines (*BRITISH MEDICAL JOURNAL*, December 13th, 1924, p 1103, and *Edinburgh Medical Journal*, 1925, 32, 67). It is particularly his letter in your issue of May 23rd, 1925 (p 987) to which I should now like to reply.

He states that a conclusion to be drawn from my experiments is that active specific immunity can only be acquired as the result of "physical suffering." What I attempted to show was that active immunity can only be acquired as the result of a reaction on the part of the tissues to the antigen injected. This reaction varies considerably depending on the antigen and the animal employed, and does not necessarily involve physical suffering. When the organism used is the pneumococcus and the animal treated is the rabbit the reaction is invariably severe, no immunity can be produced without considerable wasting. This has been well recognized by other workers. Here would seem to be the ideal conditions for establishing the practical application of the detoxicated vaccine. However it is of considerable significance that animals injected with detoxicated and defatted vaccines showed no signs of wasting or ill health, but at the same time their serums contained no specific protective properties while the animals injected with an ordinary vaccine showed a very marked reaction with loss of weight and in spite of their ill health, produced an active immune serum which was capable of protecting mice from 100,000 lethal doses of virulent pneumococci.

Dr Coplans seems to think that the weights of the animal employed have been disregarded. This is not the case. All the animals selected for comparative tests were of approximately the same age and weight.

With regard to the comparison of the quantities of the several vaccines employed, the ordinary and defatted vaccine were prepared by emulsifying definite dried weights of the organisms in saline (the method I consider most accurate for standardizing vaccines). The detoxicated vaccines were prepared by the originator of the process (Dr David Thomson), whose own standard was necessarily employed—that is the number of organisms per cubic centimetre. In order to render the various preparations approximately comparable, Brown's standards (which give the numerical equivalent of 1 mg of dried bacteria in 1 c.c. of suspension) were applied in the case of the ordinary and defatted vaccines, while enumeration by plating was used for the broth culture vaccine. The dosage of the different preparations was then arranged so that the therapeutic principle which has been applied in using detoxicated vaccines (that is, large doses considerably in excess of those generally given in the case of ordinary vaccine) could be adopted in the animal experiments.

In reference to Dr Coplans's remarks regarding the dosage of the detoxicated vaccine injected into rabbit he states that, by a simple arithmetical calculation, in one injection I must have given 1,000 c.c. of the detoxicated vaccine to a rabbit! It is surprising that anyone who considers himself capable of criticizing bacteriological research work should take up valuable space in your journal by suggesting that such a dose was ever given. However this arithmetical problem (which has arisen owing to an uncorrected error in the heading of the table of doses) will be elucidated by reading "thousand millions—38,500" as "38,500 millions."

The conclusions I have arrived at regarding the immunizing properties of these types of vaccines have been based now on a large number of animal experiments, the results of which have been exceedingly uniform and decisive on the question at issue, and I fail to see how Dr Coplans's comments in any way affect my interpretation of the results—I am, etc.

J. S. P. DAVIDSON, M.D., F.R.C.P. (Edin)

Hunth, Scotland Sept 17th

FLUORESCENCE

SIR,—Professor W. L. Dixon, in his paper on "The therapeutic value of light" as reported in your issue of September 19th (p 499), points out the important part played by fluorescent substances in the blood stream. In discussing his own view of their action, he says: "This view is entirely different from that expressed by Dr Peacock in which he regarded the fluorescence of the skin surface as a protective phenomenon, though on what evidence I do not know" (Italics mine). I should like to refer Professor Dixon to the details of my experiments (published since he read his paper) in the *Lancet* August 22nd (p 369).

It would appear quite possible for fluorescent substances to play a defensive role in the skin and an opposite one in the blood stream, as suggested by the experiments referred to by Professor Dixon. As a matter of fact in case of haematomorphinism, under the care of Dr H. MacCombe, was markedly protected by covering the exposed skin with a thin layer of vaseline, a brilliantly fluorescent substance—I am, etc.

London W 1 Sept 21st

P. REDINGTON PEACOCK

ACUTE APPENDICITIS IN THE AGED

SIR.—In the *BRITISH MEDICAL JOURNAL* of September 12th (p 479) Dr F. C. Foister reported a case of acute appendicitis in a lady aged 75. On reading his notes I am tempted to send you an account of a case that occurred in a man 80 years of age.

On June 1st 1921 Dr Smale of Pensilva asked me to admit to hospital an old man with general peritonitis due probably to appendicitis. He had been ill for four days with abdominal pain and vomiting. On admission the old man looked extremely ill, abdomen distended rigid and painful with tenderness and rigidity most marked in the right iliac fossa. Temperature 97° F., pulse 135. The family decided to take the small chance of life that operation

offered, the patient being too ill to decide for himself. A subcutaneous saline was given, also atropine gr 1/100, open ether was administered by my partner, Dr Toogood. I opened the abdomen through the right rectus sheath, removed a perforated gangrenous appendix, did not stop to bury the stump, and placed a large tube into Douglass's pouch as there was a considerable quantity of free pus present also a good deal of lymph adherent to the coils of the intestines. The abdomen was closed with through and through sutures. Recovery was normal except for some slight bronchitis, the wound became soundly healed and he is today alive and well. There was no history of any previous attack. The old man attributed his recovery largely to the fact that he was allowed to take goat's milk and cream which his sons brought him daily from the moors and to which he had been accustomed all his life.

It would be interesting to know the greatest age at which any patient has been operated upon for appendicitis. I believe that Sir Samuel Wilkes was over 80 at the time of his operation.—I am, etc.,

Li leard Cornwall Sept 16th

BRIAN B METCALFE

ADDITIONAL VOLUNTARY HOSPITAL ACCOMMODATION

Sir,—Dr Buttr (September 19th, p 540) is an advocate of trying to get the 10,000 beds required by an additional effort on the old lines. Is he not somewhat ashamed of the old methods? A "sportsman competition" simply encourages the habit of gambling. It puts temptation in the way of the poor hard-up work. It encourages dishonesty. And, after paying organizers and others, how small a proportion is left for the voluntary hospitals!

I think I saw the other day that half the income of St Thomas's Hospital now comes from paying patients. What representation on the governing bodies of the hospitals have the paying patients and the weekly subscribers? If the extra money is provided by the Government for a national necessity, why should it follow that there must be undue and harmful interference by its representatives? I have always suspected that all the silly talk about socialism and the voluntary hospitals comes largely from honorary medical officers, who think they have some sort of a monopoly in the voluntary hospitals, which they fear to lose. I have always contended that the Divisions of the British Medical Association, as representing the general practitioners, should have some say in all hospital appointments. The same honorary medical officers would howl out against any such innovation.

The committees who were elected to look after the distribution of the Government grant seemed ideal for arranging for the supply of hospital needs. I contend that the present methods are uneconomical, and unjust to good and generous citizens. The Hospitals Association has no sense of citizenship, its policy is selfish and medieval. The refusal of State aid for hospitals means a great deal of human suffering, but that, I suppose, seems a lesser evil to Conservative politicians.—I am, etc.,

Southend on Sea Sept 22nd

FERDINAND REES, M D

FOULING OF FOOTWAYS BY DOGS

Sir,—I have recently received so many inquiries from a clerical officers of health and other medical men concerning the by-law which operates in this borough in regard to the fouling of footways by dogs that I think it may be well to write to you on the matter.

In this borough there is a very large number of flats and maisonnettes to which no gardens are attached with the result that dogs are exercised on the footways. Owing to the fouling of the footways as a result of this practice, the council came to the conclusion in 1921 that it was desirable to secure legislation to enable it to deal with the nuisance. The by-law, which was finally sanctioned by the Home Secretary, reads as follows:

No person being in charge of a dog in any street or public place and having the dog or a lead shall allow or permit the dog to deposit its excrement upon the public footway.

Any person offending against this by-law shall be liable to a penalty not exceeding 40s.

The by-law was made in pursuance of Sect on 23 of the Municipal Corporations Act, 1882, Section 16 of the Local

Government Act, 1888, and Section 5 of the Local Government Act, 1899, for the good rule and government of the Royal borough.

Two officers in my department report breaches of the by-law detected by them to the Public Health Committee. These two officers are engaged on other outdoor duties, and make their observations while passing from place to place in the borough. A leaflet calling attention to the requirements of the by-law has been delivered to a large number of dog owners, a poster in similar terms has been exhibited in various parts of the borough, and a printed slip has been attached to the rate demand notices.

During 1922 two offences were reported to the Public Health Committee and a warning was issued in each case. In 1923 two warnings were issued, and in the case of a third offence a summons was taken out, the defendant being fined five shillings. In 1924 a conviction was obtained in each of the four summonses issued, in one case the fine was five shillings, and in each of the other three ten shillings.

I have no hesitation in stating that the condition of the footways in the borough has improved very considerably since the by-law came into operation. Several other boroughs have now adopted a similar measure.—I am, etc.,

JAMES FENTON,

Public Health Department
Kensington, W. Sept 22nd

Medical Officer of Health.

THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

Sir,—The Council of the Royal College of Surgeons decided on July 30th last to petition the Privy Council for a supplemental charter, among other purposes, "to admit women Fellows and Members of the College on the same terms and conditions as men, and with the same rights and privileges."

It is therefore expedient that prospective women Members of the College should realize beforehand that their so-called "rights and privileges" do not include any representation of Members as such upon the Council or in the management of the College.

Thus, too, in spite of the fact that there are over 16,000 Members most of whom are general practitioners, and that the Council of the College is composed exclusively of consultants and specialists.—I am, etc.,

London S W 6 Sept 21st

HUGH WEDD, M R C S

Obituary

SIR FRANCIS DARWIN, D Sc, M B, F R S,

Formerly Reader in Botany in the University of Cambridge

SIR FRANCIS DARWIN, the distinguished botanist and writer, died on September 19th at Cambridge after a long illness. Although he never practised medicine, he was a member of our profession and a friend of many medical men, and his teaching of elementary botany brought him into affectionate contact with generations of Cambridge medical students.

Francis Darwin was born at Down, Kent, on August 16th, 1848. He was the third son of Charles Darwin, the great naturalist, grandson of Robert Waring Darwin, M D, F R S, who practised medicine at Shrewsbury, and great-grandson of Erasmus Darwin, physician and early exponent of the doctrine of evolution. While an undergraduate at Trinity College, Cambridge, he was one of the earliest of a long line of students of science who smoked their pipes in the hospitable rooms of Professor Alfred Newton on Sunday evenings in Magdalene College. At the suggestion of E C Stirling Frank Darwin became a medical student, and began to work for the Natural Sciences Tripos, in which he gained a first class in 1870. He then entered St George's Hospital with the intent on becoming a practising physician and in 1875 graduated M A and M B. However, under the impulse of I I Klein's teaching at the Brown Institute—he gave him, as he said in after years, the chance to see "science in the making"—he abandoned the idea of medicine as a career. Accordingly, on leaving St George's he went home to Down.

as Charles Darwin's assistant, and so continued, with intervals of study at Würzburg and Strasbourg, until his father's death in 1882. In that year he was elected F.R.S. in recognition of his researches in physiological botany, and settled at Cambridge with a Fellowship at Christ's College. From 1884 to 1888 he was university lecturer in botany at Cambridge, and for the next sixteen years university reader. During this period teaching and research in plant physiology, and the organization of a sound system of practical instruction in the rudiments of botany, occupied much of his time. Under his guidance the botanical part of the Cambridge course in elementary biology for the first M.B. examination took shape, and in 1895 he embodied the gist of his class teaching in an excellent manual, the *Elements of Botany*, produced as one of a series under the general editorship of Sir Arthur Shipley. This small book was very plainly and intelligibly written, and gave a good selection of examples to illustrate the various facts and phenomena, with special regard to the medical student's need for groundwork in the basic sciences. A more advanced work, just as valuable in its way, was the *Practical Physiology of Plants*, written by him in collaboration with E. H. Acton, and published in the previous year.

The importance of Francis Darwin's experimental studies of the movements of plants will be appraised elsewhere, but mention must be made here of the admirable full-length portrait of his father's work and character, presented by him to the world in 1887 under the title *Life and Letters of Charles Darwin*. In this, as in many short biographical sketches and essays on divers subjects, he revealed both literary grace and that command of lucid statement which seems to belong by birthright to every member of the Darwin family. He once said that the best exercise in English he ever had was the correction of his father's proof sheets.

Many honours and distinctions fell to his lot. He was a doctor, *honoris causa*, of eight universities, including his own, Darwin medallist, and formerly Vice President and Foreign Secretary of the Royal Society, and President of the British Association in 1908-09. He was knighted in 1913. As for his influence with the students of medicine and pure science whom he taught at Cambridge, perhaps the most fitting thing that can be said is what he himself wrote in generous appreciation of others: "The personal effect of teacher on pupil cannot be bought at a price, nor can it be paid for in any coin but gratitude. It is the possibility of earning this payment that makes the best part of a teacher's life."

Dr. JOHN WALTON HAMP, who died on August 28th in his 74th year, received his medical education at Queen's College, Birmingham, where he obtained the diploma L.S.A. in 1876, and the L.R.C.P.S. and L.M. in 1878. After holding house appointments at Queen's Hospital, Birmingham, he commenced practice in Wolverhampton, and was elected a member of the town council in 1884. In 1900 he became mayor, and in the following year was made a justice of the peace. He was elected a member of the British Medical Association in 1877, and he was also a fellow of the Obstetrical and Medico-Chirurgical Societies of Edinburgh.

Universities and Colleges.

UNIVERSITY OF LONDON UNIVERSITY COLLEGE

On October 5th and 6th from 10 a.m. to 1 p.m. first year students of the Faculty of Medical Sciences will be received by the senior tutor, the dean of the faculty, and the sub-dean. On Monday, October 5th from 2.15 to 4 p.m. students of the Faculty of Medical Sciences other than first year will be received on the same day, at 3.15 p.m. candidates for the D.P.H. will be received by Mr. Delafield, acting head of the department. The new buildings for anatomy, anthropology, embryology, histology, and physiology, provided by the gift of the Rockefeller Foundation of New York, are now in full use. The list of public lectures includes six on "The study of man" by Professor G. Elliot Smith and Dr. C. F. Sonntag, and one on "The photochemistry of vision" by Professor Luitz Weigert of the University of Leipzig. Full particulars of the course and other public lectures may be obtained on application enclosing a stamped addressed envelope to the Secretary of the College, Gower Street, W.C.1.

Medico-Legal.

THE "ERA" CULT IN NEW ZEALAND

PRACTITIONER'S APPEAL DISMISSED

THE appeal of Dr. Henry Dundas Mackenzie, medical practitioner, of Auckland, New Zealand, against the Order of the Supreme Court of New Zealand, made on March 30th, 1925—a report of the judgement of Mr. Justice Healdman appeared in the *BRITISH MEDICAL JOURNAL* of May 30th (p. 1023)—removing his name from the *Medical Register of New Zealand*, was dismissed by the New Zealand Court of Appeal on August 1st.

The motion for removal was made at the instance of the New Zealand Medical Board, it being alleged that Dr. Mackenzie had been guilty of infamous conduct in a professional respect in practising the Abrams method in the diagnosis and treatment of cancer in such a manner as to show that he could not have honestly believed it was a reliable or useful method in the cases in which he employed it.

Judgement of Appeal Court

Mr. Justice Sim, in his written judgement in the Court of Appeal, said the Medical Practitioners Amendment Act 1924 provided in Section 6: "That no medical practitioner shall be deemed guilty of grave impropriety or infamous conduct in a professional respect by reason only of his having adopted and practised any theory of medicine or surgery if in so doing he has acted honestly and in good faith." The court was of opinion that the judgement of Mr. Justice Healdman was right. Appellant's counsel had complained that his client had been condemned because he relied almost entirely upon the Abrams system and very rarely resorted to ordinary clinical methods. Complete reliance on the system might be foolish and reckless, but it was quite consistent with honesty and good faith. Another complaint was that Mr. Justice Healdman had based his decision to some extent on the report of the Horder Committee on the Abrams system and that it was not fair to judge Dr. Mackenzie's conduct during the years from 1921 to 1924 in the light of a report which was not published until 1925. This contention seemed to be well founded. The question of the value of the Abrams system was not directly in issue in the case, the only question being whether Dr. Mackenzie had acted honestly and in good faith in his use of that system. Appellant's counsel had, therefore, succeeded in some respects in establishing that the reasoning by which Mr. Justice Healdman had arrived at his conclusion was not entirely sound. Notwithstanding this, however, that conclusion appeared to be justified by the evidence, from which it was clear that although Mackenzie might have believed to some extent in the Abrams system, he used it not for the purpose of benefiting the unfortunate sufferers who came to him for relief, but for the purpose of exploiting them to his own pecuniary advantage. Mr. Justice Sim added that the order fixed two years as the time after which Mackenzie might apply for re-registration. It was unfortunate he thought that any period was fixed, for it seemed undesirable that such a practitioner as Mackenzie by obtaining registration again should be enabled to prey on a gullible public.

Mr. Justice Alpers, in concurring said if he had tried the case he would have fixed the period for re-registration at ten years instead of two.

The Services

SURGEON LIEUTENANTS R.N. FOR SHORT SERVICE

THE Admiralty announces (A.O. 2677) that surgeon lieutenants R.N. entered for short service on completing two and a half years service, are required in future to forward a statement through the usual service channels as to whether they desire to serve for twelve months after the termination of their three years engagement for short service. Surgeon lieutenants for short service who have completed over two and a half years service at the date of the receipt of this order should send in their statements immediately.

EAST AFRICAN MEDICAL SERVICE

The Secretary of State for the Colonies has approved of the following changes of title in the staff of the Medical Departments of—

Uganda. Principal Medical Officer to be Director of Medical and Sanitary Services. Deputy Principal Medical Officer (Native Services) to be Deputy Director of Medical (Native) Service. Deputy Principal Medical Officer to be Deputy Director of Medical Service. Chief Sanitation Officer to be Deputy Director of Sanitary Service. Sanitation Officer to be Senior Sanitation Officer. Surgeon in charge European Hospital Kampala to be Surgical Specialist. Bacteriologist to be Director of Laboratory. Medical Officer of Health to be Sanitation Officer.

Tanganyika. Principal Medical Officer to be Director of Medical and Sanitary Services. Deputy Principal Medical Officer to be Deputy Director of Medical Service. Senior Sanitation Officer to be Deputy Director of Sanitary Service. Senior Medical Officers of Health to be Senior Sanitation Officers. Medical Officers of Health to be Sanitation Officers.

Zanzibar. Principal Medical Officer to be Director of Medical and Sanitary Services. Senior Medical Officer of Health to be Senior Sanitation Officer. Assistant Medical Officer of Health to be Sanitation Officer.

Medical News.

THE annual dinner of St George's Hospital Medical School will be held at the Hyde Park Hotel on Thursday, October 1st, at 7.45 p.m., with Dr F. Ashton Warner in the chair.

THE Fellowship of Medicine announces that the second weeks of the intensive course in medicine, surgery, and the special departments at the Westminster Hospital, and of the course in diseases of the chest at the Brompton Hospital, begin on September 28th. On September 30th Dr C. B. Heald will give the second of his series of four lectures on electrotherapy. The Fellowship of Medicine has arranged a series of lectures on tuberculosis in the lecture room of the Medical Society of London, 11, Chandos Street, the opening lecture will be delivered on October 12th, at 5.30 p.m., by Dr L. S. Burrell, on tuberculosis from the physician's viewpoint. There is no fee for this series, and all members of the medical profession will be welcomed. The following other courses will be held in October: diseases of the throat, nose, and ear, at the Central London Throat, Nose and Ear Hospital, with an operative surgery class, a course in tropical medicine, consisting of eight clinical demonstrations, on Tuesdays and Thursdays, a combined course in diseases of children at the Paddington Green Hospital, Victoria Hospital, and Children's Clinic, a course in urology at St. Peter's Hospital, and a course in dermatology at St. John's Hospital. Copies of the syllabus of any course may be obtained from the Secretary, 1, Wimpole Street, W.1.

THE Infants' Hospital and the National Association for the Prevention of Infant Mortality and for the Welfare of Infancy have arranged a course of postgraduate lectures on infant care for health visitors, nurses, midwives, and superintendents of infant welfare centres. The lectures will be given in the lecture hall of the Infants' Hospital, Vincent Square, Westminster, S.W. on Mondays, at 6.30 p.m., from October 5th to December 21st. A syllabus and tickets may be obtained from the Secretary, National Association for the Prevention of Infant Mortality, 117 Piccadilly, London, W.1.

A SERIES of three lectures is being delivered at the Royal Free Hospital on the application of Christianity to the doctor's life. The standpoint of a general practitioner was dealt with by Miss A. Lloyd Williams on September 17th, and that of a consultant on September 24th by Dr H. Crichton Miller. The non-medical point of view will be expressed by Canon Simpson, of St. Paul's Cathedral, on September 29th.

THE Deptford Borough Council is organizing a health exhibition which will be held from September 28th to October 2nd. Besides various exhibits, addresses, and film displays, lectures will be given by the medical officer of health (Dr C. S. Thomson), Dr Leckard Hill, Dr E. Sloan Chessel, Mr E. B. Turner, and others.

THE annual meeting of the Medical Sickness, Annuity, and Life Assurance Society will be held at the offices of the company, 300, High Holborn, W.C.1, on Monday, October 12th, at 4 p.m.

THE opening of the eighty-fourth session of the School of Pharmacy of the Pharmaceutical Society of Great Britain will take place at 17, Bloomsbury Square, W.C.1, on Wednesday, October 7th, at 3 p.m. The Pereira Medal will be presented, and the inaugural sessional address will be delivered by Dr Winifred Cullis, Professor of Physiology in the University of London.

ON September 15th the Mayor of Lewes unveiled a tablet in the Council Chamber of the Lewes Town Hall to the memory of Dr J. R. Stenhouse, late medical officer of health, and founder of the Lewes Sanatorium.

DURING the first four months of this year 1,128 cases of typhus, with 118 deaths, occurred in Rumania.

The thirty-fourth French Congress of Surgery will be held at Paris under the presidency of M. Berard, professor of clinical surgery at the Lyons Faculty of Medicine, from October 5th to 10th. The following subjects will be discussed: (1) remote results of the different methods of treatment of cancer of the rectum, introduced by MM. Guadier of Lille and Anselmo Schwartz of Paris; (2) treatment of tuberculosis of the knee after adolescence (15 years), introduced by MM. Fredet of Paris and Vignard of Lyons; (3) the present apparatus used for fractures of the humerus and femur, introduced by MM. Guyot of Bordeaux and Rouvillot of the Army.

IN view of the general importance of town planning the part of the annual report of the Ministry of Health for 1924-25 which deals with this subject has been published separately. Copies may be purchased, price 6d., from the Stationery Office, Adastral House, Kingsway, W.C.2 or through any book seller.

THE issue of the *Nederlandsch Tydschrift voor Geneeskunde* of September 12th has a special supplement containing the papers delivered in English, French, German, and Italian at the plenary sessions of the fourth International Congress of Industrial Hygiene recently held in Amsterdam. Sir Thomas Oliver's address was printed in our issue of September 19th (p. 530).

ON the advice of Professor Pirquet active immunization of school children against diphtheria with toxin antitoxin has been forbidden in Austria.

THE proposed provincial meeting at Leeds of the Society of Superintendents of Tuberculosis Institutions has had to be abandoned. The ordinary meeting of the society will be held in London in October on a day to be announced later.

THE well known histologist Professor Camillo Golgi of Pavia celebrated his 82nd birthday on July 9th.

ON the occasion of his 60th birthday Professor Max Askanazy, director of the Institute of Pathological Anatomy at Geneva, was the recipient of a special number of the *Revue médicale de la Suisse romande* containing fourteen original articles dealing with pathology.

THE Sunderland Division of the British Medical Association has arranged a scientific meeting to be held at the Royal Infirmary, Sunderland, on Wednesday, October 7th, at 7.30 p.m. All medical practitioners in the area of the Division, whether members or not of the Association are invited to be present.

Letters, Notes, and Answers.

All communication in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their name, not necessarily for publication.

Authors desiring PLIPINS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *JOURNAL* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are: *MUSUM 3361* "G" 3363, and 3364 (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES

EDITOR of the *British Medical Journal* *Histology Westcent, London*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.) *Histology Westcent London*

MEDICAL SECRETARY *Medicina Westcent London*

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams: *Bacillus Dublin* telephone 4737 Dublin) and of the Scottish Office 6 Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh* telephone 4361 Central).

QUERIES AND ANSWERS

RECURRENT THROMBOSIS

"SCOTUS" asks for advice in a case of recurring thrombosis in the legs. The patient a man of 50 has slight varicose veins in the calf in both legs. The thrombosis occurs chiefly in the femoral veins. Milk has been given up and lemon juice is taken freely.

CLIMATE FOR SURGICAL TUBERCULOSIS

"G. H. S." inquires whether there is a locality on the mainland near Southampton suitable for a case of surgical tuberculosis. He already has information regarding the Isle of Wight.

PREVENTION OF MIGRAINE

DR H. M. TRAQUAIR (Edinburgh) writes. In reference to the inquiry by Dr Cheater (September 12th, p. 493) it may be remarked that pressure on the chiasma does not produce homonymous hemianopsia. The hemianopsia associated with migraine is entirely different in type from that caused by sub-geniculate pressure interference. Nor does pituitary swelling—unless very gross—cause increased intracranial pressure.

DR HENRY BAZZETT (Torquay), in reply to Dr Cheater's request for information as to how attacks of migraine may be prevented writes. My routine treatment if followed regularly, seldom failed. It was based on the observation that, in practically every case of migraine a history of ancestral gout could be obtained and on the experience of the benefit derived from "flushing the system" with well diluted lemon juice. In both that disease and rheumatism I invariably ordered the

taking for the remainder of life, the juice of half a lemon in a tumbler of water unsweetened, on an empty stomach, night and morning. My two worst cases so treated were (1) A business man of over 30 with very violent fortnightly attacks. (2) A lady of over 60 in poor circumstances and working as a housemaid, with a very bad gouty history, who had had bad attacks at about the same interval as (1) since early girlhood. No 1 remained for years entirely free from attacks on this treatment, but he temporarily abandoned it when an exceptionally severe attack quickly followed. No 2 told me about a twelve-month after she commenced the practice that she had only had one attack in that twelve months, and that a very slight one. Both occurred in my practice at Hendon, which I left not long after, so that I can only speak of their immunity from attacks during the year or two I had them under observation. Their surprise and gratitude were extreme.

ANSWERS TO THE FACT

"R. H. B." writes to remind "A. B." whose query on this subject was printed on September 12th (p. 498) of a practical note on the treatment of acne vulgaris by Dr. James Ait Scott consulting dermatologist to the Ministry of Pensions, West Midland Legion, which appeared in our columns on January 26th, 1924 (p. 159).

TREATMENT OF VARICOSE VEINS

Dr. J. NISSEI, D.M.C. (London) writes with reference to Dr. H. T. Gibson's inquiry (September 19th, p. 545).—A multipara aged 29 with generalized varicosity of legs and vulva of seven years' standing sent me to hospital at the end of August. I was written from the Hotel des Thermes to say: "I have just finished ten baths and am going strong. I haven't felt my legs since I came although they were very bad at Dinard. The arthritis in my hands has completely gone and my joints are quite supple now. The cures are simply a wonder in people with phlebitis etc. come in to the baths on stretchers and after about a week can walk quite well. It is getting too cold here now for we are about 800 feet up and the sea is freezing. I shall come next year in June." She adds that the baths begin with three at 20 minutes, two at 25 minutes and the rest at 30 minutes; and that these last are preceded by 25 minutes of cold painful spraying of the legs. The patient rests for two hours after the bath. Before breakfast 10 minutes of adrenaline solution are taken by mouth (1/2 inch) because the gastric vaso constriction induced prevents absorption) and before lunch and dinner a tablet of phlobose (1/2 composition). A glass of Vittel water is drunk before and after each bath and again at bedtime. The hotel is opposite the baths and the terms are 65 francs a day inclusive.

INCOME TAX

Cash Receipts or Bookings

If I. C. has been in his present practice for five years during which time the profits have been assessed on the basis of the actual money received. The inspector of taxes is now asking for a statement of book debts.

The profits assessable should strictly be assessed on the basis of the value of the fees booked but it is understood that the Revenue authorities are willing to accept the cash receipts basis unless there is ground for supposing that that basis would for some reason give an appreciably different result. Presumably the Inspector is enquiring for the statement of outstanding debts at different dates to see whether the amounts are substantially the same. If they are, then the two bases will in the long run yield the same result and no doubt the inspector will continue to accept the cash basis figures. Unfortunately the statements asked for are often difficult to prepare for a medical practice especially as receipts should be made for specific debts believed to be paid wholly or in part, and if I. C. might find it advisable to see the Inspector first and discuss the matter with him if—this would seem to be the case—there is no particular reason for thinking that the amount of uncollected fees is increasing.

Private Use of Car

If S. V. is entitled to certain allowances in respect of his motor expenses but the inspector refuses to allow more than 1/3 of the full amount on the ground that the remaining one third is covered by private use of the car.

We gather that H. B. V. does not contend that since 1923 the car may have been used for private purposes in the ratio suggested. If that was not the case in 1923 and earlier years we are of opinion that a different proportion should be taken for the "renewal" allowance, but the "depreciation" allowance refers to the year of assessment itself. We cannot, of course, offer an opinion on the merits of the ratio taken, it is certainly at an unusually high figure but its correctness or otherwise depends entirely on the facts of the case.

Depreciation of Car

"J. P." inquires what depreciation allowance he is entitled to in respect of his car.

The rate normally taken for the purpose is 15 per cent on the written-down value of the car for 1925-26. "J. P." will

be entitled to 15 per cent of £240 (the cost price of his car) = £36, and for the following year 15 per cent of (£240 - £36) = 15 per cent of £204—that is, £31, and so on.

LETTERS, NOTES, ETC.

"I GOT A D B S"

SIR JOHN O'CONNOR, M.D. (Buenos Aires), writes: In a leading article on international radiology in the *British Medical Journal* of July 11th, 1925 (p. 75) I read with deep interest that "the day of the foot and toe surgeon has passed." It happens that I was the parent of the paraphrase "foot and toe" (vide "Ligation of simple fractures" *Annals of Surgery* January, 1915). I accept the sentence in the past tense, passed, the leader writes, and I am delighted to think that diagnostic accuracy has reached such a high standard in England as to render ordinary employment of the exception which I believe is still the dominant mode in radiology—an unnecessary, if not antiquated, factor in surgical diagnosis.

SUBJECT OF THE TREATMENT

Dr. G. D. FRY (Medical Superintendent, Dumfries and Galloway) writes:—With reference to P. A. D. S. 29th (p. 402) I would suggest that the abnormal temperature be based on a more definite knowledge of the normal before treatment is undertaken. Referring to the so-called normal temperature, I can cite an example (On the Metal Thermometer and Thermography) of *Healthy Man during Post-Caric Institute of Washington*, 1910 (p. 177) says: "It is some time to place the exact limits of the rectal temperature of this man (33.4) and it may be local upon the more or less of a thermometer which has been so shipped by long continued use." In their work the describe the normal temperature as under 36.5, a regular rhythm during the day, lowest in the early morning rising to a maximum in the afternoon and falling thereafter. They further state that a high temperature several condition is not to be forgotten that this point—fluctuations amounting to as much as 2°—may well be within the range of physiological limits and in no way indicative of pathological condition. Reference to these and other observations—for example, Woodhead and Varrier Jones *Lancet* 1916 p. 452, 1 reads (1) and (2) in (1) of *Asyria*. The following working rules laid down by Prof. J. of *Asyria*. The rectal temperature in the healthy (adult) individual on waking in the morning is near but below 37° C. During the day it rises to 37.5° C. but remains below 39° C. (the subject being in bed). In the evening it falls between these two readings. In the female subject the rules apply during the post-menstrual cycle, but there is a physiological rise of about a degree during the pre-menstrual ten to fourteen days. The oral temperature is about 0.9° C. lower than the rectal and is much less reliable for small variations. Persuaded and back strikingly demonstrate that for oral thermometry the mouth must be kept shut for ten minutes before and the thermometer retained therein for at least another five minutes. The axillary temperature is lower still and least reliable. In conclusion I would strongly advise that the diagnosis of subnormal temperature be established by rectal or fasting that careful oral thermometry before, thyroid or other treatment is contemplated. If P. A. D. S. is unconvinced and without time to look up references I would earnestly suggest that he observe his own temperature on an "off" Sunday. Apart from the subject under discussion general acceptance of such data on the above and other observer would revolutionize the domestic treatment of pulmonary tuberculosis. The importance of this is a matter of distress to those of us who are almost entirely guided by them in the sanatorium part of treatment.

HEALTH AND SERVICE

One of the activities of the Health Service Bureau of the Wesleyan and Central Assurance Society, Birmingham, is the preparation and distribution of literature bearing upon personal and civic hygiene. We have received copies of leaflets dealing with the following subjects: Cancer, tonsils and adenoids, diphtheria and scarlet fever. These describe the ways in which these diseases begin how they spread point out warning signs and give simple advice about nursing. Similar leaflets have already been prepared on first aid, influenza, measles and infantile diarrhoea. These are not the only activities of the Health Service Bureau of this assurance society. For a more detailed and comprehensive setting up machinery for the study of mortality and morbidity statistics and for making periodical health surveys. It professes that whatever will promote better health and longer life is within the range of the service.

VACANCIES

NOTIFICATION of officers vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 33, 34, 35, 36, and 37 of our advertisement columns and advertisements in partnerships, assistantships and locum tenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 116.

British Medical Association

PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, BATH, 1925

SECTION OF MEDICINE

The Right Hon Lord DAWSON OF PENN, G C V O, K C M G, C B, M D, F R C P, President

PRESIDENT'S OPENING

LORD DAWSON, in opening the proceedings in the first day's session of the Section said

Although the days of lengthy inaugural addresses—and perhaps to our profit—are passing, I hope you will agree it would be fitting for me to spend briefly by way of introduction to the proceedings of this Section

First, let me say how highly I value the honour of being President of the Section of Medicine, for service in medicine is always an honour and a joy to those who love their profession. This Annual Meeting may be said to be notable—notable in that it records substantial advance in the knowledge of malignant disease, the fear of which rarely escapes our home at some time or another, and we enjoy the proud thought that such has come as just reward to British investigators, notable because this Association is giving expression to the realization of the widening range of its usefulness in the domains of learning, education, and public good, notable for gathering in this ancient city, rich in traditions which inspire its citizens, and not least its doctors, with wisdom and courage in meeting the problems of the day.

This is not the occasion to discuss the brilliant researches into cancer which are occupying our interest, but the fact of general import emerges that before the virus can invade an animal there has to be created in that animal a factor or nidus which will enable the virus to get foothold, and, what is remarkable, this factor or nidus is more specific, more individual, than the virus itself. The virus has a measure of interchangeability as between animal and animal, but the internal factor belongs exclusively to one domain. This brings forth in graphic manner what is always being borne in upon clinicians—namely, the individuality of disease, or rather how individual, how varied is man in his reactions to morbid processes—a fact which is worthy of remembrance even by those who are concerned with systems of government. And the way in which this internal chemical factor conditions the growth of cancer emphasizes the fact that with the advance of the acute infectious medicine will be concerned more and more with the condition of the individual man—his resistance, his qualities, which make for good and for evil.

So medicine will occupy itself increasingly with the fascinating but difficult study of trends and tendencies, with the border country between the physiological and the pathological, and this will in its turn bring medicine more in contact with how man thinks, and acts and feels, and plans—in short, how he has his being—and will make those who seek man's well-being feel the need of its co-operation. It follows that though the outlook of medicine will alter, its horizon will widen. Its disciples will be inspired as always by the unceasing quest for knowledge, and, on the other hand, by the bringing of the wisdom of that knowledge to man's service, as the prophets but not the vassals of sixteen hundred years ago.

Before concluding I would like to pass from thought to the man, and yet the change is not abrupt when one recalls that the man who is in our minds gave brilliant expression to the thought. I refer to Clifford Allbutt. He was not only physician and thinker, but a great leader for this Association during the troublesome years of the war. There were gathered within him many attributes forming an harmonious whole of rare beauty—wide knowledge, ripe scholarship, broad outlook, the living faith that to-morrow will be better than to-day. Moreover, he possessed in a manner exceptional if not unique, the physical beauty which can belong to advanced age. The greatest tribute

to age is the allegiance and affection of the young, and these were his in supreme measure. His was the glory of the setting sun—now living, refulgent, and then passing in a few moments behind the horizon—leaving us in abiding influence and grateful memory.

DISCUSSION ON
RHEUMATOID ARTHRITIS, ITS CAUSATION
AND TREATMENT

OPENING PAPERS

I—SIR HUMPHRY ROLLESTON, BART, K C B, M D, Regius Professor of Physic in the University of Cambridge, President of the Royal College of Physicians of London

The subject of what is commonly called rheumatoid arthritis is especially appropriate at Bath, with its long historical association with the treatment of joint disease, its special hospitals, and its wealth of clinical material.

For this discussion the designation "rheumatoid arthritis" may be taken to cover the group of chronic joint affections of uncertain nature, but it has been considered convenient to leave aside the condition of advanced osteoarthritis, especially of the hip in old people, though it must be admitted that such a condition may be the outcome of the rheumatoid arthritis. Fibrositis, which Stiedemann says always precedes, and in any case is much the same as rheumatoid arthritis except that, like paronychia, it concerns the connective tissues other than those in or about the joints, may, in order to reduce the already extensive scope of the subject, also be omitted. Regarded in this somewhat arbitrary fashion rheumatoid arthritis is, like splenic anaemia, a repository for syndromes not proved to be specific. The subject is so enormous that it is obviously impossible to touch on all its numerous aspects.

ETIOLOGY

The present conception of the disease is that it is infective, but it may be well to consider if infection is the sole and exclusive factor.

The Question of Disordered Metabolism

In 1907, while admitting that treatment of focal infections is sometimes followed by amelioration or even cure of the affected joints, Sir Archibald Garrod—son of Sir Alfred, who in 1858 introduced the name "rheumatoid arthritis"—doubted if these cases are really examples of the specific disease rheumatoid arthritis, adding the cautious proviso, "assuming that such a specific disease exists and not examples of other forms of infective arthritis which mimic it more or less closely", and in 1923 he was of much the same opinion in opening a discussion at the Royal Society of Medicine, at which Cassidy expressed his firm conviction that the importance of infection had been greatly exaggerated and, while granting the existence of a large group of chronic infective arthritis believed that there was also a genuine rheumatoid arthritis—a somewhat uncommon disease probably due to disordered metabolism. The question, then, is, Are all forms of chronic arthritis with the exclusion of the nervous arthropathies in its types and symptomatology, gout, leucophilic and possibly psoriatic arthropathy (Garrod and Evans) to be regarded as due to infections with various micro-organisms of a low virulence, or ought an open mind to be still maintained as to the existence of cases independent of microbial infection from the start and due primarily to some disorder of metabolism analogous to gout as commonly accepted?

What evidence is there that disordered metabolism is the sole cause of rheumatoid arthritis or of a certain group of cases in this category? Hereditary disposition to arthritis is not a very strong argument and what is much the same though in even broader conception, the "arthritic diathesis" is not a very satisfactory conception, for they both might be regarded as, in other words, an inherent want of resistance to infection. Joint changes have been described in a few rare cases of that "inborn error of metabolism" alcaptonuria and ochronosis. According to Pemberton (1921), the basal metabolism is

lowered in 20 per cent of the cases, and the sugar tolerance is lowered in rheumatoid arthritis but it might justly be argued that this really depends on infection as it returns to normal abruptly on removal of the focal infection. The blood fats and cholesterol, the blood calcium, and the blood urea and non-protein nitrogen were found to be normal. From his point of view, then, the metabolic defect appears to be limited to the carbohydrates, and even then might be regarded as, in common with the arthritis, due to infection. It is impossible to deny that an inherent disorder of metabolism might favour in infective or toxic arthritis by diminishing the resistance, and that gouty deposits are found in chronic rheumatoid joints, though they may be secondary rather than primary. On the other hand, it is known that an infection may, by inducing pancreatic disorder, lead to a more or less permanent lowering of sugar tolerance. Pemberton (1925) considers that such a permanent lowering of sugar tolerance accounts for the disappointing results of removal of definite foci, it might therefore be logically argued that a lowered sugar tolerance alone should also cause rheumatoid arthritis. But rheumatoid arthritis is not a feature of diabetes mellitus, even though infections are prone to occur, so that as regards disorder of carbohydrate metabolism as a primary factor in the causation of rheumatoid arthritis the positive evidence is very weak. Although infection may so affect the endocrine glands as to modify metabolism and thus favour joint changes, this is very different from postulating a primary error of metabolism independent of infection. G. Diaper (1920) argues that chronic arthritis represents a very profound constitutional disturbance in forces analogous to those concerned in acromegaly and thyroid insufficiency, and chronic arthritis due to thyroid insufficiency (Leopold-Levi and Rothschild-Sergeant) and to pluriglandular inadequacy, especially ovarium (Umber), has been described, but it might be objected that chronic infection is really the underlying factor of both the endocrine and the arthritic disorder. The endocrine element in arthritis has recently been discussed by H. K. Thompson who divides the cases of arthritis into (a) isotrophic or chronic infective arthritis due to and curable by removal of, the infective focus, and differing structurally from the two following forms—(b) atrophic or rheumatoid arthritis occurring in individuals of the slender "carnivorous" type of Goldthwaite and Bryant, and associated with, but he does not say definitely due to, some evidence of endocrine dysfunction, often hyperthyroidism; (c) the hypertrophic or osteo-arthritic of our attacking the "herbivorous" type of Goldthwaite with low metabolic rate, benefited by iodine medication and showing evidence of hypothyroidism. It will at once be obvious that as osteo-arthritis and hypothyroidism are both common in advanced life, their coincidence does not prove that the joint lesion is secondary to the thyroid disorder. Thompson does not prove or, indeed, dogmatically claim more than that "certain types of arthritis are not necessarily disease entities but may be symptoms of, or coincident with, an endocrine dysfunction." Correspondence between the geographical distribution of endemic goitre and rheumatoid arthritis (McCarrison) and the disposing influence of hypothyroidism which has been regarded as identical with the arthritic diathesis (L. J. Llewellyn 1925) might be explained by the view that they are both results of an underlying endocrine infection.

Infective Origin

The effects of oral sepsis, largely due to W. Hunter's advocacy and more recently to Billings's book and Wilcox's papers, are now well known, and its association with arthritis is fully recognized, but this advance has occurred well within the lifetime of many of us, and the importance attached to it has progressively increased. The relative responsibility of the teeth and the tonsils has been variously estimated: the teeth and gums have been incriminated for 50 per cent of the cases (Beddard Wilcox 1923), Lillie and Lyons from a series of 200 consecutive cases of tonsillectomy for arthritis possibly a one-sided experience, considered the tonsils responsible for 79 per cent of the

arthritic cases. Pemberton (1921), on the basis of 400 cases, gives percentages of 52 for the tonsils and 33.5 for the teeth. Possibly they are about equally responsible, and they certainly may both be diseased in the same patient, but, as the tonsillar and peritonsillar infection may be secondary to the dental, the latter should perhaps be given the first place. Adenoids should of course be considered in the same category as the tonsils. With regard to the teeth, a distinction has rightly been drawn between (1) pyorrhoea, in which the infective agents are discharged into the alimentary tract and are therefore prone to set up secondary foci in the tonsils, and, if there is achlorhydria, in the gall bladder, intestines, appendix, but are not so likely to pass into the general circulation and reach the joints as in (2) apical infection of the teeth, which may occur in teeth superficially healthy and so require skiagraphic assistance for their detection, here, being in a closed space, absorption by the blood is more likely to take place. A secondary focus in the maxillary antrum may be due to local extension of dental infection, and it is important to eliminate both foci. It would be interesting to have statistics showing what proportion of cases of rheumatoid arthritis are associated, on the one hand with pyorrhoea alone and on the other hand with the apical infection of the teeth only, I am informed that it should not be difficult to obtain cases with pyorrhoea but without any trace of apical infection. It is perhaps still necessary to emphasize the importance of remembering that the accessory nasal sinuses may be the sites of infection responsible for arthritis, sinusitic infection may be secondary to oral, dental, or pharyngeal lesions, or, conversely, it may be primary and give rise to them. It seems probable that unless the exit of discharge, purulent or otherwise, is obstructed sinusitis is, like pyorrhoea alveolaris, more likely to cause gastroenteritis and secondary foci in the gall bladder and vermiform appendix than systemic and arthritic infection. Cases of sinusitis responsible for arthritis may be latent and escape attention, and Dr P. Watson-Williams believes that it is the slighter, rather than the profuse purulent, forms of sinusitis that cause arthritis, because they are not accompanied by a polymorphonuclear leucocytosis which protects against the effects of absorption. For the detection of infection of the accessory sinuses transillumination and skiagraphy may be misleading and are not so satisfactory as puncture.

The activity of intestinal bacteria largely depends on the presence or absence of hydrochloric acid in the gastric contents. Achylia gastrica has been described in rheumatoid arthritis by Knud Faber, Woodward and MacLennan, Wallis, and Hurst. Coates and Gordon, adopting Hurst's explanation of the relation of subacute combined degeneration of the spinal cord to Addisonian (pernicious) anaemia, suggest that in rheumatoid arthritis achylia gastrica allows the bacterial production of a toxin with a special predilection for the synovial membranes.

Intestinal auto-infection has been urged, especially by Sir Arbuthnot Lane, as a cause of chronic arthritis. Pemberton (1914), from numerous laboratory investigations, found that protein putrefaction is not a factor. But Mutch has developed Lane's conception on bacteriological lines. In 1915 he found intestinal infection with staphylococci in Still's disease, later he insisted on a long-chained streptococcus as a pathogenic intestinal organism, and the observation, made in 1921 by N. and J. Mutch, of its characteristic glycolytic character or avidity for sugar, is of great interest in connexion with Pemberton's successful results in restricting the carbohydrate intake of chronic rheumatoid patients. Mutch, like Lane, insists on the frequency of masked stasis and hidden infection in the intestinal tract of patients with rheumatoid arthritis. Beddard, however, considers that in the absence of signs, such as attacks of diarrhoea, pointing to infection of the intestinal mucosa, this is improbable. Primary infections of the colon, such as dysentery, have been considered to be rarely responsible for rheumatoid arthritis in this country, the great majority of colonic infections being secondary to oral infections. On general principles intestinal infection should be restrained by the antitoxic function of the liver from producing secondary changes in the joints, though it is possible that

in certain cases bacteria might pass via the thoracic duct into the general circulation and so escape the hepatic filter. It would be interesting to know the results of tests for phenoltetrachlorophthalein test, in cases of severe chronic infective arthritis.

Infections of the genito-urinary tract, excluding those of gonococcal origin, do not play a prominent part in the production of arthritis, but it may occur in *Bacillus coli* infections of the urinary tract, and streptococci from chronic and vesicular seminales, and attention was called by F. McCrae to prostatic infections as a cause of arthritis, especially of the spine, and among 100 cases of chronic arthritis in the prostate infection of the vesicular seminales may extend from the prostate, and, though often gonococcal or tuberculous, may be due to other micro organisms.

Infections of the respiratory system have attracted comparatively little attention as a cause of chronic arthritis. Pierre Marie's chronic pulmonary osteoarthropathy is, of course, a well marked example. Mention should be made of Poncet and Leclerc's view, apparently widely accepted in France, that the commonest form of chronic infective arthritis is that due to the toxins of a distant tuberculous focus acting on the joints, 50 per cent at least of the cases ordinarily met with are thus explained (Mouriquand and Michel), the joint affection being, in fact, analogous to a tubercule of the skin. This conception of the widespread influence of tuberculosis has received little recognition and is still uncertain—namely, whether it is entirely toxic, the joints never being infected—and also because it is so different from ordinary tuberculous arthritis. H. Platt could not find any conclusive evidence that it is a pathological or clinical entity. Probably many would agree with his dictum that Poncet's disease is merely chronic arthritis in a person with tuberculosis, but even then it should be borne in mind that the joint lesion might be modified by the presence of a tuberculous focus elsewhere, further, the long debated and now established syphilitic nature of tuberculous should warn us to keep an open mind in the relation of tuberculosis to chronic arthritis of doubtful origin.

Skin infections such as boils may be responsible for rheumatoid arthritis, and Stockman has seen it in general dermatitis and lupus erythematosus, but whether or not chronic arthritis may follow impetigo or nephritis has done (Guiraud J. Phillips) is an interesting point. The etiology of psoriatic arthritis has given rise to some discussion. Guiraud and Evans remark that the rapid recovery of the joints when the psoriasis clears up is unlike anything seen in cases ordinarily classed under the name rheumatoid arthritis and is only approached in severe cases of dysentery. This is perhaps evidence of the success of removal of a primary focus rather than of their contention that neither lesion is a mere complication of the other. But possibly psoriatic arthritis is a toxic or anaphylactic rather than an infective arthritis, and the association of intermittent hydrarthrosis with two out of Guiraud and Evans three cases is at least compatible with this view.

Consideration of Criticisms of the Infective Theory of Rheumatoid Arthritis

It has naturally been urged against the focal infection theory of rheumatoid arthritis that extensive infection, especially oral, may exist for a long time without the sequence of rheumatoid arthritis or other systemic lesions, and indeed it has been stated, probably with considerable truth that few persons of mature years are entirely free from chronic septic foci. Further it has been insisted that in many cases of rheumatoid arthritis careful search fails to reveal a septic focus. In considering why very definite focal infection often fails to cause joint lesions, the contribution of the individual, his powers of resistance must be taken into account, the moral now well recognized in the case of tuberculosis, that the seed (the local conditions of the joints) as well as the soil (the infective agent) is an important factor in determining whether or not disease

results, should be more extensively applied in rheumatoid arthritis. Cases certainly occur in which a focal infection exists for years before the onset of arthritic phenomena, which may then run a rapidly progressive course, crippling the patient in a few years. Something, perhaps an attack of influenza, has broken down the individual's immunity and powers of resistance, among which the bactericidal power of the gastric hydrochloric acid must be taken into account, or in a more marked degree has rendered him sensitive to micro organisms or to foreign bacterial proteins to which he was previously immune. Another example of this required susceptibility is provided by cases following acute trauma, or the long continued stresses and strains described by Sir Arbuthnot Lane.

But the disposing factor may be inherent and congenital, such as the anatomical conformation of the body and "the human constitution," which G. Dupier (1924) has recently defined as "the aggregate of hereditary characters, influenced more or less by environment, which determines the individual's reaction, successfully or unsuccessfully, to the stress of environment." Goldthwaite and Bryant described two types of departure from the normal which they called the enervous, from their slender figure, and the herborious—broad backed, heavy, and prone to degenerative diseases, such as uterine sclerosis, diabetes, and osteo arthritis. The narrow backed slender type are prone to tuberculous and other infections, many intestinal disorders, and, significant on these counts, rheumatoid arthritis. Crookshank in an able paper argues that in persons prone to become chronic arthritis there is often some morphological defect which renders a joint a place of diminished resistance. He gives examples of congenital rheumatoid joints showing definite evidence of congenital defect, such as malformed little fingers, small thumbs, and pleonostose famillae as an extreme instance of deformity favouring subsequent disease, and Collet's observation of a congenital condition of the hip joint approaching dislocation, as a disposing factor to senile arthritis of the hip. The nervous origin of rheumatoid arthritis (Latham, 1886) describing the changes to disturbed trophic action though now mainly of historic interest, may apply in a few instances—for example, in Chiriac's arthropathy—by rendering the joints a *locus resistencie minoris*.

It must be admitted that it is often difficult to detect the infective focus. This may depend on imperfection in our means of localizing them—for example, the necessary nasal sinuses, prostate, vesicular seminales, or the internal female genital organs, may escape investigation, cryptic infection of submucosa or apparently normal tonsils may easily be overlooked, or there may be a closed focal infection of the gall bladder or appendix which may remain latent, not discharging then bacteria into the alimentary canal, so that bacteriological examination of the faeces may not give any clue. Another difficulty about focal infections is that the primary one, such as dental suppuration may produce secondary foci, some of which are less easily removed—for example in the tonsils cervical glands, maxillary antrum, the gall bladder, appendix, intestine, mesenteric gland, a reservoir of infection. Mutch (1925) divides the infections of the alimentary canal into two zones—the upper, of the mouth and throat the lower of the bowel and its appendages the second may be local or affect the whole from the duodenum to the rectum. Thus extrication of the teeth may fail to relieve the joint symptoms because a secondary focus of foci have become active in distant and unsuspected parts. Thus in a series of 80 cases of arthritis recorded by Bloch, 42 patients had had some focal infection removed but all of them still had other foci remaining, 25 had lost their tonsils, and 22 of these still had infected teeth. One reason for the practical—namely, as regards rheumatoid arthritis is perhaps imperfect removal of the whole of the focal infection. Dentists are rightly conservative in extracting teeth they believe to be sound but if even one tooth with latent apical infection is left this may be sufficient to keep up the joint trouble, either by carrying as a continued source of bacteria conveyed by the blood, or possibly merely by providing poisons which, acting on a

joint rendered hypersensitive by previous infection, responds actively (vide infra). Even when teeth are removed infected roots may be left behind to keep on the evil influence, thus, among 290 edentulous jaws, M F Lusterman found 129 root or other evidences of infection, and he believes that 37 per cent of the areas to which dentures are adapted harbor infection. The position is made more difficult by evidence that x-ray examination of the jaws may fail to reveal infection of the apices of the teeth (Meisser and Hiden).

An objection sometimes raised to the infective origin is that the average run of rheumatoid cases show little or no evidence of corresponding systemic and visceral damage. In reply it may be said that this is also true of many cases of undoubted focal infection. But, on the other hand, rheumatoid arthritis is often associated with fibrositis and neuritis, and in the juvenile form of rheumatoid arthritis, or Still's disease, the lymphatic glands are commonly and the spleen often enlarged, and occasionally visceral lesions are found in the kidneys and in rare instances in the liver.

If for the purpose of this discussion rheumatoid arthritis be regarded as a subacute or chronic inflammation of the joints due to infection, but not proved to be due to any definite bacterial agent, so that gonococci, pneumococci, and other known bacterial forms of arthritis are excluded, then it appears that, logically, an arthritis of chronic course associated with streptococci or staphylococci invasion of the tonsils or apices of the teeth and cured after removal of the focus and corresponding vaccine treatment, should be excluded from the group of joint affections of obscure origin for convenience described as rheumatoid arthritis. In general, however, this apparently logical sequence is not observed, and such a case, presumably streptococci, is not removed from the category of rheumatoid arthritis. There is some reason for this want of strict consistency: the streptococci form a large and even yet, from their instability, imperfectly classified group, and among the various forms some only are responsible for chronic joint lesions. The difficulty in the specificity of the streptococci makes it reasonable to wait before transferring these cases from rheumatoid arthritis to streptococci arthritis.

A point of interest for discussion in the clinical phenomena of rheumatoid arthritis is how far toxic influences, as apart from continuous or repeated infection of the joints, play a part. A joint is infected, and as the result of local and other treatment the condition subsides, whether the causal organisms die out or remain late it being unknown. Is it not conceivable that the joint becomes hypersensitive and, in the event of any toxin reaching it from an infective focus, such as a single tooth with apical infection, reacts in an anaphylactic manner? There are other examples of a probable anaphylactic arthritic reaction, such as intermittent hydrarthrosis and possibly gout.

BACTERIOLOGY

The infection is obviously of low virulence and of a very chronic nature. Various organisms have been found in cases of rheumatoid arthritis, which would thus appear to resemble bronchitis and colitis in being not specific but due to a number of different infections, and therefore including a number of different diseases, though clinically in many ways alike. Various streptococci are most frequently incriminated.

In 1914 Hastings found that out of a series of cases 17 gave a positive and 18 a negative complement fixation test of *Streptococcus viridans* and therefore considered, what would now be regarded as a very modest estimate, that 40 per cent of the cases of rheumatoid arthritis are infective. Among Mutch's 200 cases of intestinal infection in chronic arthritis the vast majority were streptococci only 6 per cent of which were hemolytic. From 21 cases examined in the course of laparotomies it appeared that the small intestine was the site of streptococci invasion; a transition to *B. coli* infection taking place about the ileo-caecal valve. It might thus be assumed that streptococci responsible for arthritis might not be recovered from faeces passed per anum. Beddard spoke of the long-chained organism *Streptococcus longus* as present in 75 per cent of the cases.

Staphylococci appear to be much less often responsible than streptococci.

In 1903 Dor obtained *Staphylococcus pyogenes albus* from the joint of a rheumatoid patient. Crowe described as a causal agent *Staphylococcus epidermidis albus* (variety *deformans*) or *Micrococcus deformans* and has obtained agglutination of their

own scurf cocci by their blood in patients with severe rheumatoid arthritis. Among Mutch's 200 cases 4 per cent only were associated with staphylococci.

Other microorganisms, such as coliform organisms, have been described.

A natural objection to the infective nature of chronic arthritis is the difficulty of obtaining microorganisms from the joints, even when they are obtained from chronic cases, as Poynton and Paine (1902) did, it might well be argued that the infection has supervened in a joint rendered a place of diminished resistance by the arthritic change, and that the experimental production of joint changes in animals by the injection of such an organism does not prove that the original arthritic changes in the patient were due to the organism. That the fluid removed from rheumatoid joints is almost always sterile is not surprising from analogy with the same event in tuberculous pleurisy, but the unity with which cultivation of pieces of synovial membrane removed from such joints gives a positive result in spite of the numerous media employed is a problem deserving further investigation and consideration, if the view that rheumatoid arthritis is due to a chronic infection rather than to a toxic or metabolic factor is to be maintained.

TREATMENT

Treatment is primarily preventive—namely, the hygiene of the mouth and other sites of focal infection. Dental disease and oral sepsis have probably become more frequent with the more widespread consumption of soft foods, and it may be that rheumatoid arthritis has correspondingly increased, on the other hand, the school clinics for dental treatment and the removal of tonsils and adenoids are a step in the direction of preventive medicine and should exert a neutralizing effect. Removal of teeth with apical infection is obviously essential, and, as already mentioned, all affected teeth should be removed, otherwise the arthritis may continue and the result be disappointing. The patient should be warned that the extraction may be followed by a temporary aggravation of the arthritis, general infection may result, and in a recent case the possibility that the preliminary injection of a local anesthetic had favoured this complication by more widespread damage to the tissues was raised. Whether or not the affected teeth should all be removed at one sitting or extracted in relays should be decided in each case by consideration of the patient's condition and to some extent by the number of the teeth affected. Leucopenia has been regarded as a sign of diminished resistance (K Gordby, J A Tonen) and an indication that not more than one tooth should be removed at a time. Removal of dead teeth requires careful consideration: dead pulps favour persistence of infection and so arthritis, Lord Bennett emphasizes the responsibility in this respect of dental surgeons who kill sensitive pulps for the relief of pain. Cauterizing of an infected uterus is dangerous, as it may spread the infection.

Before vaccine treatment is commenced infective foci that can be dealt with, such as the teeth and tonsils should be removed. Autogenous, not stock, vaccines should be employed, and sensitized vaccines have their advocates. When more than one organism is suspected to be responsible for the arthritis, it has been suggested that monovalent vaccines from them should be given so as to recognize the causal one by reaction in the joints, but mixed vaccines may be necessary. Vaccine therapy is often combined with, and said to be helped by, diathermy and ultra-violet radiation (Billington). Crowe's results with his *Micrococcus deformans* vaccine showed that 70 per cent of 62 patients were cured for the time, and that 15 of these, or 25 per cent of the total number, were known to remain so.

Intestinal auto-intoxication has been attacked by many disinfecting drugs, especially guaiacol. In cases with aetiology gastrica hydrochloric acid by the mouth is a logical procedure in inhibiting bacterial activity in the alimentary canal, and stasis has naturally been met by purgatives—paraffin and so forth. Sulphur is an old intestinal antiseptic, intramuscular injections of sulphur in oil have been given by Reinmann and Pucher, who are somewhat erudite in their estimate of the effects, and of organic sulphur compounds, contramine and thergamine have been recommended from a different standpoint by McDonagh, who says

that their effect is as striking as that of insulin in diabetes, but that their oral administration is ineffectual.

Thyroid extract and arsenic, as in so many obscure conditions, have been given, and may do good by speeding up metabolism, which Pemberton believes to be lowered as regards carbohydrates. H. W. Nott obtained a cure in 8, relief in 14, and no benefit in 11 out of 33 cases treated by rectal injections of potassium permanganate and the oral administration of thyroid extract—the permanganate being thought, by its detoxicating action, to enable the thyroid extract to exert its effect. On the other hand, parathyroid, the action of which is antagonistic, not complementary, to that of thyroid extract, has been found to be beneficial (Grove and Vines), and is said to act by correcting the disturbance of the endocrine balance between the thyroid and the parathyroid, in which the parathyroid becomes subordinate, with calcium deficiency which is due to chronic infection (Vines). The administration of parathyroid one-tenth of a gram, which is not regarded as a specific remedy, appears to be more effective than the intramuscular injection of calcium salts. The number of drugs that have been given is long, it includes iodine as a tincture or in colloidal form by the mouth, or intravenously, and colloidal preparations of sulphur and manganese. It has been suggested that iodine does good merely by improving the condition of the thyroid and relieving subthyroidism, which favours arthritis (Llewellyn, 1925).

Pemberton, finding that there is a lowered sugar tolerance more or less in proportion to the severity of the arthritis, has employed a dietetic treatment based on restriction of carbohydrates and a reduction of the total caloric value of the food intake, with due attention to the state of general nutrition. Within four days of a diastolic reduction of the diet subjective improvement may occur, even though a septic focus is present, and this dietetic regime appears to enable other methods of treatment, such as hydrotherapy, to exert a beneficial effect which they fail to effect alone. Red meat, tomatoes, apples, and bulky foods of small nutritive value, so as to make an appearance of a fairly generous diet, are allowed. This method is specially applicable to cases in which a focal infection is not found. As convalescence advances cautious improvement of the diet may be tried. As regards diet Llewellyn Jones in 1909 insisted on the mistake, due to confusion with gout, of restricting meat, but in the absence of dyspepsia did not restrict the carbohydrate diet.

An important point in treatment, which the orthopaedic surgeons have impressed upon us, and on which Sir Robert Jones will no doubt lay stress, is the prevention of permanent deformities from the adoption of bad positions of the limbs and trunk during the acute stages and exacerbations. As has been well said by Russell the price paid by the patient for comfort during the acute phase is that of becoming a cripple for life. Unless carefully supervised, complete immobilization of the painful joint by plaster or splints, may lead to troublesome fixation of the articulation and the patient should therefore be urged to move the joint as early as possible, or passive movements and massage should be employed. Forcible extension of the joints in order to break down adhesions is a process attended with risks. But in the stage of convalescence suggestion and encouragement in moving the affected joints are important.

The good effects of heliotherapy and ultra-violet radiation natural or artificial, are explained in various ways—namely, by increasing the bactericidal power of the blood and so raising the resistance to infection (Rollier, Colebrook, Eidinow and Leonard Hill) or also by speeding up metabolism. There appears to be some difference of opinion about the influence exerted on basal metabolism. Pemberton (1925) says that it is increased by external heat, Aigyll Campbell that it is unaffected by a light bath. Hall has obtained surprisingly gratifying results in various forms of arthritis from ultra-violet radiation provided by the tungsten arc lamp, combined with other forms of electrotherapy such as general diathermy and ionization. Other forms of external treatment—by massage, heat, and hydrotherapy, such as whirlpool baths—do good by increasing the supply of blood to the joint thus improving the local resistance and so possibly killing off the local infection

and it has been suggested that this is due to the increased oxidation processes thus favoured (Pemberton).

Protein Shock Therapy.—The intravenous injection of foreign protein in various forms, such as Witte's peptone (Auld), milk, and especially T A B vaccine, so as to produce a relatively severe reaction (protein shock), has been employed with some success—at any rate for a time—in rheumatoid arthritis. Some of the benefit ascribed to the specific effect of vaccine treatment may, as L. Baker remarks, be due to protein shock. Cruickshank has obtained encouraging results from the intramuscular injection of 0.3 to 0.6 gram of peptone in solution on four or five occasions at weekly intervals so as to give rise to a temperature of 101° F. Draper (1920) suggests that the good effects of the domestic remedy bees' stings in rheumatoid arthritis are due to protein shock therapy. Improvement after protein shock therapy depends on the occurrence of a febrile reaction for twenty-four to forty-eight hours, and is often accompanied by exacerbations of the arthritis, like that sometimes seen after removal of septic teeth, though rigors are commonly present, the reaction is very rarely dangerous. It has been suggested that the improvement is due, not to one, but to various factors, such as alteration in the ferment and anti-ferment balance in the blood serum, leucocytosis, fever, sweating, and increased lymph flow (Jobling and Petersen), and a resulting increase in the defensive powers of the body, it has been compared with the effect of an acute intercurrent disease on a chronic infection (D. Campbell), or an example of one disease curing another, such as malarial infection on general paralysis of the insane. In early cases the infection may be cut short, or it may be inhibited only, so that the disappointment of relapses after improvement can be explained by recrudescence of the infection. Campbell has treated 100 cases, 70 of which, up to November, 1923, he has analysed, of these 70 there was no improvement in 12, in 58 benefit was obtained so that 40 of them were in work without relapse after periods of one to three and a half years, while 16, and possibly 2 that had been lost sight of, had relapsed. As the infection may be inhibited only and not abolished by protein shock therapy, he suggests that it may be wise to give one or two more injections after the active phase has disappeared.

QUESTIONS FOR DISCUSSION

The following points may be suggested for discussion

1. Is rheumatoid arthritis always infective in origin?
2. What is the relation of tuberculosis elsewhere to chronic arthritis?
3. What share do constitution and disorders of metabolism take in its causation?
4. Are the arthritic and endocrine disorders both due to infection, or does metabolic disorder sometimes precede and dispose to infective arthritis?
5. Treatment by endocrine therapy, dietetic modifications, and protein shock.

II—W R ACKLAND, M R C S, M D S,

Dental Surgeon Bristol Royal Infirmary Lecturer and Examiner in Dental Surgery Bristol University.

SIR HUMPHRY ROLLESTON has described oral sepsis as the product either of pyorrhoëa which drains into the mouth, or of apical infection which does not. In other words, pyorrhoëa produces an open or free sepsis, and apical abscess a closed sepsis.

But though this is true in the main, as a matter of experience we find the deeper layers of pyorrhoëa do not drain, and on the other hand, an apical abscess may burst into the mouth in the familiar "gumboil." Hence both open and closed sepsis are occasionally produced by either pyorrhoëa or apical infection or by both. It is important to recognize that pyorrhoëa does not ever entirely drain. Deep pockets and shut-off foci exist whose products may enter the circulation.

A young woman came to me with apparently a perfect set of teeth, every one of which was attacked by pyorrhoëa, there were no dead teeth. At first she had no constitutional symptoms, so I attempted to keep them except for one or two of the worst. But the patient gradually lost weight, got joint symptoms with an evening temperature round about 100°. In the end I had to extract them all.

It has been estimated that pyorrhoëa affecting the thirty-two teeth to the depth of 1/8 inch produces an absorbing raw surface of 2½ square inches in area. If the four lower incisors are alone involved to their full extent 3 square inches of absorbing area result. If all thirty-two teeth are fully involved in the disease it has been shown that the enormous area of 20 square inches is offered to absorption.

Open sepsis, which is so horribly obvious in many patients seems to be tolerated for years without much apparent harm. But on close examination we find all

effects somewhere in the alimentary tract—tonsillitis, laryngitis, pharyngitis, gastric, hepatic, and pancreatic inefficiency. I believe intestinal stasis may be caused by the weakening of the muscle of the intestinal wall.

We are accustomed to say that the healthy gastric juice will destroy the streptococci, but there is no proof that the endotoxin is destroyed. Indeed, there is the greatest probability that the endotoxin is liberated by the destruction of the streptococcus. It is further probable that a healthy gastric juice is gradually broken down by this open sepsis, and achlorhydria may result. As a matter of fact, what probably happens is that through the night, when the stomach walls are resting and the gastric juice is not being produced, the sepsis is still being poured along the alimentary tract, and it produces its effects on gastric walls and the rest of the tract unhindered. These patients tell us that they get up good for nothing in the morning, with no appetite. They frequently suffer from insomnia and temperature.

Open sepsis, then, may be a most insidious and potent predisposing cause of arthritis, partly by providing extra foci of infection, partly, too, by its impairment of the hepatic function through duodenitis and cholecystitis, and in general by weakening resistance. But the closed sepsis, especially that of apical infection, provides the purest culture of streptococci, and an "overload" on the one hand and weakened resistance on the other, allows the poison to enter the circulation.

You realize that it is a tooth whose nerve is dead which alone becomes the seat of apical abscess.

Research has shown that the *Streptococcus viridans* has an elective affinity for dead teeth. He devitalized dogs' teeth and injected a vaccine from apical infection of a human tooth at various parts, and always found the streptococcus in close apposition to the devitalized teeth.

Finally, then, I offer the following points for consideration.

- 1 That pyorrhoëa never entirely drains
- 2 That even a healthy gastric juice may not destroy the toxin

3 That a healthy stomach exposed to open sepsis will break down in time

4 That inasmuch as the liver is one of the most important producers of antibodies, impairment of the hepatic function by oral sepsis is likely to be a predisposing cause of arthritis

5 We get a "flare-up" of the arthritis after the extraction of teeth. Equally we get a "flare-up" with too large a dose of vaccine prepared from dead teeth

6 These cases are disappointing because even when the dental or other foci have been removed, one cannot remove at once the effect of the long years during which immunity has been breaking down. In other words, if a man has suffered from septic teeth for ten years, you may remove the bad teeth, but you cannot suddenly put him back ten years. The most you can hope for is that for the present he shall not get worse.

As regards treatment, we naturally begin by taking skiagrams of the teeth, with especial reference to bridges and crowns. One has, however, to realize that x-rays are not an infallible guide, and apical infection may exist without much appearing in the skiagram.

In cases then, of arthritis, we condemn all crowns, bridges and dead teeth, whether the skiagram shows mischief or not.

In one case I have had the patient under observation for two or three years and only extracted one or two of the worst every three or four months, as they successively became loose and tender with pyorrhoëa, at which time the joints seemed to "light up" and become tender.

It has answered very well in this particular case, though as a rule one gets rid of the teeth more quickly. I am bound to say, however, that these cases are often the most disappointing as the patient frequently gets such a reaction, and is often so depressed by the inability to eat or speak properly, not to mention the disfigurement.

Vaccines as a remedy for pyorrhoëa are useless, in my experience, but as a part of the treatment after extraction a vaccine is most useful.

III.—RUPERT WATERHOUSE, M.D. M.R.C.P., Consulting Pathologist Royal United Hospital Bath Physician, Royal Mineral Water Hospital and Royal United Hospital Bath

I HAVE been invited to continue this discussion with special reference to the experience that those of us who practise in Bath require of the treatment of this disorder by balneological methods.

The hypothesis that rheumatoid arthritis is dependent on the presence of some septic focus was in full swing in Bath a quarter of a century ago, and it might be imagined that preventive and curative measures in the direction of the eradication of septic foci resulting from the increased care of the teeth, removal of diseased tonsils, etc., would in that course of time have led to an appreciable diminution in the incidence of the disease. For all I know this may be the case, but there is certainly no evidence of it in Bath, indeed, it seems to me that sufferers from this crippling type of arthritis form each year a larger proportion of those who seek relief here. This is a personal impression only, for our hospital statistics are of very little value for this purpose, owing to the constantly changing nomenclature of these chronic joint affections. Especially have I been struck with the large number of cases met with in men since the war, and though here again I am unable to bring forward figures in support, I am inclined to think that the disproportion between the sexes is less than it was, say, twenty years ago.

In my remarks I shall employ the term as it was first, I believe, used by Sir Archibald Garrod and exclude those cases in which bony outgrowth is a feature from the outset, such as Heberden's nodes, the lipping of the knees so often met with in middle life, and disease of the spine and hip characterized by the presence of osteophytes, cases of which he made a separate group under the heading of osteo arthritis. This distinction is, I am sure, one of real value, for whilst in both the presence of septic foci militates against recovery, the symptoms, course, and prognosis of the two affections are quite different.

Unfortunately the position is complicated by the occurrence of intermediate cases of all grades, the correct classification of which is a matter of the greatest difficulty, some, indeed, may be a true admixture of the two, but this need not prevent our recognizing the fact that at the two extremities of the scale there are two affections utterly dissimilar, and one cannot help thinking that those who claim such uniformly successful results from any particular form of treatment include many cases which here in Bath we should classify, not as rheumatoid, but as osteo arthritis, cases in which the natural tendency to quiescence is much greater.

Of the importance of the elimination of septic foci in the generalized, fusiform, peritonsillar, atrophic type of arthritis with which we are dealing there can be no question. I have seen cases recover, apparently completely, after removal of diseased teeth and tonsils, after cure of a prostaticitis, after the healing of a rectal ulcer, and after appendicectomy. But the percentage of cases that completely recover as the result of such measures is, in my experience, very small. For one who can thus be described as "cured" I should say there were nine who could only be said to be "improved." As Sir Humphry Rolleston has pointed out, the focus may be of such a kind or so situated that it cannot be eradicated. But the fact I wish to stress is this: that these patients even after removal of their teeth and tonsils, after treatment with vaccines, serums, proteins, and what not, still find their way to spas in numbers as large as if not larger than, even so that it is doubtful whether much more is to be expected from treatment on these lines until our methods of detecting and dealing with the responsible focus have considerably advanced.

The results of spa treatment of rheumatoid arthritis, using the term in the restricted sense and excluding cases of osteo arthritis, are somewhat comparable to those obtained by dealing with septic foci—that is to say, a very few cases are cured by one course of treatment, whilst the great majority can be said only to be relieved or temporarily improved. But it is only very exceptionally that some benefit is not received, and although in severe cases

there may appear to the casual observer little change in the patient's condition, it means much to the bedridden sufferer himself to be able to walk a few steps without assistance, to be able to feed himself where formerly he had to be fed by others, or, in the case of a woman, to be able to do her own hair, though this latter accomplishment is not, of course, so important as it was a few years ago. I would submit that these are, from the patient's point of view, no small gains to be achieved as the result of a few weeks' treatment. For unfortunately the period over which a course of treatment of this kind can advantageously be extended is limited, and treatment too prolonged is apt to produce debility and undo any good that had previously resulted. Six to eight weeks is generally considered as much as any patient should receive at one time, and sometimes not more than three or four is advisable.

But if the essentially chronic nature of the malady is appreciated, and these patients can be induced to come for further courses with intervals of a few months' rest in between, the results are eminently satisfactory, further improvement occurs with each course, and I have known many instances where patients apparently doomed to hopeless crippledness have eventually been able to resume their occupation.

There are, however, obstacles in the way of following this, which I regard as the ideal, course in those cases where, after thorough investigation, careful treatment of septic foci has failed to cure the complaint. In the case of hospital patients lack of accommodation is the bar. For many years there was a rule at the Royal Mineral Water Hospital that no patient should be readmitted until two years had elapsed, and since even at that time the waiting list was so long that a patient had often to wait seven or eight weeks for admission, it may seem to have been justified. Of late this rule has been relaxed with, in individual cases, the happiest results, but it must not be forgotten that every such readmission prolongs the waiting period for others, some suffering from complaints more rapidly and completely relieved than the intractable one we are considering. In fact, for example, of 706 women who applied for admission room could be found for only 404—little more than half.

In patients above the hospital class the matter of expense becomes the important one, for this form of arthritis is far more common among those of limited means than among the well-to-do. Those who can then their own living—governesses, nurses, school teachers, and the like—are more often victims than their wealthier sisters, and can seldom afford the expense of repeated courses of spa treatment, indeed, then financial resources are often strained to the utmost to achieve one so-called "cure" of three or four weeks. In severe cases it must not be thought that even by repeated courses recovery is to be expected, but I do think that by these means, used judiciously, the complaint can as a rule be kept within reasonable limits so that the subjects of it can lead useful lives and avoid complete helplessness.

One must indeed be very cautious in ever speaking of complete recovery in a well-mixed instance of this disease. Even so far back as the days of Troussier and Sir Alfred Garrod cases were met with where, after apparent cure for several years the disease again flared up under some depressing influence, and the same is true to-day, so that it is as important for one who has had rheumatoid arthritis as for one who has had tuberculosis to regulate the whole of his or her future with a view to preventing recurrence.

Treatment of rheumatoid arthritis by hydrological or rather balneological measures resolves itself into an attempt (1) to combat any existing infection and promote elimination of toxins (2) to restore tone to the nervous system, (3) to improve the nutrition of the joints and muscles.

The first indication may be met by the douching and spraying of parts the seat of infection—for instance the nose, pharynx, vagina, colon, etc.—and cases are not infrequently met with where a pharyngitis or a vaginal discharge quickly clears up by these means after resisting skilled treatment by experts for many months. This may probably be attributed rather to the greater mechanical efficiency with which such treatment can be applied at a well-equipped spa than to any specific qualities in the medium employed, though it is possible that radio activity, or some agent of

which we are at present ignorant, may play a part. The drinking of large quantities of natural mineral water on an empty stomach may conceivably increase the output of toxins by the skin, kidneys, and bowel, apart from any specific effect that these natural radium-containing waters may possess.

No one who has had much experience of this complaint will deny the importance of a nervous factor in its causation. From the earliest times observers have been struck with the frequency with which it attacks, for instance, women who have nursed a child relative through a long and trying illness. The disease once started, the constant pain, the helplessness, and want of sleep, all tend still further to increase the nervous debility, which is further enhanced by the too kind attentions of anxious friends, who do everything in their power to spare the sufferer effort so that soon she drifts into a condition of almost complete immobility. Much can be done by well directed treatment at a spa to rouse the patient from this condition of inertia, which reacts adversely on the joints by depriving them of the nutritional stimulus of active movement. When a joint is acutely inflamed it should be rested, but when its surface is not hot, but cold to the touch, it is our experience here that, however swollen it is, benefit results from active movement, probably in consequence of the increased vascularity thus occasioned. If one of these joints is kept immobile too long as the cartilage becomes in part or wholly destroyed the ends of the bones become welded together, but if movement is persisted in a fresh articulation is formed by churning of the ends of the bones. *Post-mortem* examinations in this disease are few here, but I have more than once seen, as the result of the displacement of the proximal phalanx, a new joint surface formed in this way on the palmar surface of the head of the first metacarpal bone.

Time does not permit of my entering into a detailed description of the various methods at our disposal for relieving pain, facilitating movement, and improving the vascular supply of joints and muscles, and you will have during the week abundant opportunities of seeing them demonstrated at the Bathing Establishment, so I will content myself with stating that in my experience during the more acute stages great benefit may accrue from the electric reclining bath, but that the treatment *par excellence* for this class of case is the combination of douching and massage introduced here from A. J. Le-Bras.

IV—ROBERT B. OSGOOD, M.D., Professor of Medicine Harvard University

I APPRECIATE the courtesy you have shown in allowing me to take part in the discussion on this subject. I have little to bring to it other than the impressions of a group of physicians, who are frequently consulted when other methods of treatment have failed to restore function. Such study of "end-results," however, may not be without suggestion. Certain it is that we see many cases in which an apparently systematic and thorough removal of all possibly infective surgical foci has been accomplished, and yet the disease has not been cured or its progress checked.

In Pemberton's war cases possessing one or more such foci, actually a greater percentage of those who did not have their foci removed recovered on a general and dietary regime than of those that did have them removed. This does not necessarily imply that a chronic, distant, low-grade infection may not play an important part, but at least that there is probably some link in the chain of causative factors which in many cases is still lacking. This link has been suggested by Dr. Hans Zinsser, professor of bacteriology at the Harvard Medical School. I should not like to commit him to the statements which I am about to make but as far as I am able to recall they represent the drift of a very informal conversation I had with him just before I left America.

Sir Humphry Rolleston has hinted at the possible link by suggesting that a hypersensitive joint may react in an anaphylactic manner to a toxin reaching it from an infective focus.

We may dismiss the direct infection of joints as having no direct relation to the problems of chronic joints, nor do

acute febrile conditions apply. Bacteria may possibly play a part in chronic rheumatism in one of three ways.

1. Through thrombosis and because of endarteritic changes in joints in the course of an infectious disease.

2. By means of the toxic changes. We know many poisons are species specific—for example, 1/10 ccm of 1 in 500 to 1 in 2,000 dilution of streptococci (Dick test) may be very toxic for man but not at all for rats and mice. There may be toxins from human tonsils or teeth, for example, and these toxins may not only have a species specificity, but also a tissue specificity.

3. Allergy may be concerned. Faber was able to sensitize joints by injecting non-bacterial extracts into joints several times at intervals of one or two weeks with little or no local joint reaction. But when bacteria themselves were injected into these animals intravenously these sensitized joints became affected.

In order for animals to become allergic (not at all the same thing as the protein reactions) to bacterial material it is not sufficient that they be injected with soluble extract substance of bacteria. This allergic reaction only occurs when there is a tissue response to infection—that is, you cannot make a guinea-pig react to tuberculin by injecting it with filtered extract of tubercle bacilli, but it may become delicately susceptible to tuberculin in two weeks if you give it living tubercle bacilli, that is, there is no tuberculin reaction without the presence of the tubercle bacilli. It is easy to render a guinea-pig allergic to streptococcus filtrates by giving it several peritoneal injections of living whole streptococci in a course of two or three weeks to a month. Now, whenever the body harbours a definite focal infection, this focus, if it continues for two weeks or longer, or is frequently repeated, may make the body allergic or hypersusceptible to bacterial substances which are given off by the growing bacteria which are absorbed. These substances, however, may have slight or no activity for normal animals.

Allergic reactions under these conditions have been produced with many different forms of bacteria. Given this possibility, you have a mechanism on the basis of which it is at least logical to assume the possibility of injury to tissue remote from the focus of infection purely by the mechanism of a chronic infection followed by the mechanism of allergy. This, however, does not complete the chain of occurrences. It does not appear as if the joint cavities and the inner joint structures were, under normal conditions, in direct connexion with the circulating blood as far as the non-diffusible colloidal materials are concerned. There would seem to be some other factor in operation before this could be possible. Now, in most rheumatoid conditions there has been a clinical connexion with endocrine disturbance, exposure to cold, etc., which may well act as a capillary instabilizer and disturber. We know from allergic work that one of the basic physiological changes that underlie these reactions is a permeability of the capillaries. The toxic factor and the direct action may be possible when there is a coincidence with some other disturbance—endocrine, loss of balance, cold, etc.—which makes possible the escape of the substance from the capillaries into the circulation and into the joints or tissue spaces or lymphatics, and an allergic reaction might do the same thing if some focus—for example, intestinal infection—were present which rendered the body susceptible to this particular poison. Perhaps the "rhumatisme tuberculeux" of Poncet might be thus explained.

As regards treatment, we know of no specific drug. We are finding the basal metabolism is lower than normal in repeated tests in a larger proportion of the rheumatoid cases than we had expected, and that they seem to tolerate well and improve on carefully graded doses of thyroid extract. We have not had the success with non-specific protein therapy which Professor Stockman and Dr. Campbell have recently reported.

While we undoubtedly should attempt to eradicate every focus of infection which may judiciously be held responsible for, lowered vitality, we are inclined, as Haldane suggests, to treat the disease rather than only to search for the etiological organism, hoping by heliotherapy and attention to "body mechanics" to bring the patient to a point

where his natural defensive forces may overcome the infection agent, and he may regain his lost "capillary control" (Pemberton).

May it not be quite possible that many of the so-called foci of infection are the result and not the cause of the lowered general resistance, and that if this resistance can be raised, as we believe it often may be, we may reasonably expect that many of these foci will disappear without direct medical or surgical attack?

One thing more. May we ask for "fair play" in the prevention of deformity? We see much of this, and can offer only imperfect correction for that which might have been completely prevented. Is it not fair to ask you to learn the simple methods of prevention yourselves, or to seek help before the deformities become fixed deformities? By these measures you will save the patients from later falling into our somewhat impotent hands.

V.—**SIR ROBERT JONES K B E, C B, F R C S,**
Lecturer in Orthopaedic Surgery, Liverpool University.

The remarks I make will be confined to the prevention and correction of deformities. Sir Humphry Rolleston has dealt very completely with the disease in its etiological and histological aspects, and has especially emphasized its infective origin so that most surgeons will be in sympathy with his conclusions. The disease, or group of diseases, has a very distinct surgical aspect and should from the very earliest manifestations receive the conjoint attention of both physician and surgeon. It is rarely the surgeon has an opportunity of seeing these cases before deformities have occurred. Indeed, a walk round the wards will generally reveal the rheumatoid case, especially of the more acute type with flexed hips, flexed knees and the feet in equinovarus. In addition, there is often marked adduction of the thighs. Such cases are very difficult to deal with later, and often result in unkylosed joints. It is rarely we find the hands in any better position than that of palmar flexion with ulnar deviation, both at the wrists and at the metacarpophalangeal joints, it is not uncommon to find the forearm even pronated, which adds considerably to the helplessness of the patient. It must be our object to prevent these deformities by every means at our command. When crippling deformities have occurred a great deal can be done, even in extreme cases, to improve the conditions from a functional standpoint. Treatment, therefore, should be preventive and reconstructive.

As in every type of arthritis, muscular spasm is the starting-point of deformity, and in the extremities the flexor group of muscles are dominant—in the ankle the calf muscles plantar flex. They are assisted by the fact that slight flexion of joints is also the position of rest and of ease. If the muscles continued merely to hold the limbs in very slight flexion, and at the same time secured for them sufficient fixation to control pain, we would be satisfied to leave matters at that. As a matter of fact, this is not so for the muscular spasm is intermittent and during sleep is partially relaxed, and the deformity is always progressive because of the overaction of the stronger groups. During the later stages this is of necessity accentuated when walking is attempted because of the influence of superincumbent body weight. During the early acute stages of the disease the oncoming of deformity is overlooked, whereas no should realize from the beginning that unless prevented extreme deformity must be expected. I would suggest that the treatment of the so-called rheumatoid group should be similar to that of all other types of infected joints.

I will first say a few words on the subject of prevention. As there is no time to enter into detail regarding the separate treatment of each joint it is proper to emphasize the necessity of applying the principle of rest in relation to them all. It is to prevent movement that the muscles become protective during the acute and painful stages, and this must be looked upon as Nature's somewhat crude endeavour. We should take this indication, realizing that friction of tender joint surfaces means irritation and further effusion which is again protective. We know from experience the deformities which arise and from the first we should oppose them. This means that no

posture should be allowed which gives a bias to their development. The wrists should be kept dorsiflexed, the hips slightly abducted and extended, the knees in complete—or almost complete—extension, the ankles at right angles. From the first the wrist should be kept dorsiflexed, the metacarpophalangeal joints and phalanges just short of full extension, and the thumb slightly flexed and adducted. The hand should be kept, in short, in very much the same position as it is when it holds a large tumbler. When the acute symptoms have passed the dorsiflexion splint should be shortened in order to give play to the fingers and to the metacarpophalangeal range. There are two reasons for this position, the first and most important is that flexion of the fingers is much more powerful when the wrist is dorsiflexed, and secondly, the wrist in plantar flexion should be avoided for aesthetic reasons. Bandages should be very lightly applied in order to prevent circular compression, which hinders the circulation. The elbow should be kept slightly extended beyond a right angle, and the forearm short of complete supination. To prevent flexion at the hips the patient should not be allowed to sit up in bed, but pillows should be placed under his head (unless the spine is affected) and the head of the bed raised. This can be effected with the limbs in slight abduction by means of careful nursing, helped, perhaps, by a few sandbags without the application of splints—although splints may sometimes be needed. The feet should be kept dorsiflexed by means of skeleton rectingulum splints, and light splints may be required for the knees. The methods by which this is effected, however, are not so important as the principle governing them—namely, that rest in the position opposed to deformity should be recognized as essential. Whatever splints or methods are employed to keep the joints at rest in good position, they should be so constructed as to give easy access for any additional treatment, such as gentle massage or outward medication. Compare this with what is the general practice, even when a patient is under the charge of excellent nurses. Little effort is made, other than the very natural one of giving ease to the patient. Pillows are placed under the knees, sitting up in bed is frequent, the bedclothes often rest upon the feet, and the thighs are very much abducted. Let it be remembered that deformities are very easily prevented if we start at once during the acute or subacute stage, but they soon become very intractable.

When the acute stage is passed gentle movement may be of advantage, and here I would emphasize that pain should be avoided. Furthermore, the joint must only be moved to a limited extent once or twice a day, and the movement should be a single one. There is no object, but much harm, in repeating the movement several times on the one occasion. The movement is intended to prevent the formation of adhesions, and, if they have occurred, gently to stretch them.

If, unfortunately, joints have become deformed and the acute or very painful stage has passed, it is the surgeon's object to place them in a good position with a view to function. This he usually does by means of a splint, and he should endeavour to be very gentle in his methods. In the case of the knee if the flexion is not too acute nor the tibia dislocated brief words, a splint of the type of a Thomas knee splint will suffice, which is more easily controlled than a weight and pulley and is less apt to produce an intermittent strain. When the knee attains the desired position it can be kept without extension and gently moved. If the joints still tend to flex the control should be maintained for weeks or months as required.

There are two types of the disease which surgeons encounter—one of which is characterized by effusion, and the other where effusion is only rarely present. Richardson and Nicholls classified the one as proliferative arthritis, and the other as degenerative. The degenerative is most common in the young and effusion is neither an essential nor a frequent symptom. The x-ray picture shows a bone with diminished lime shadow, mottled and stippled, and where osteophytic overgrowth is not present to any extent. It is generally polyarticular.

The degenerative type, which occurs usually in older people, is not so commonly polyarticular, and may be confined to one or more joints. If it commences in the fingers it is

more apt to become polyarticular than if it begins in one of the larger joints. The x-ray plate shows marginal hooks and projections due to osteophytes. From the surgical aspect these two types have considerable importance. The proliferative or dry type merits a less favourable prognosis, its course being more acute and rapid and the end-result more prone to firm ankylosis—often bony in character. It runs a more rapid career of destruction than does the degenerative group. From the surgical aspect it is more difficult to treat because the ankylosis occurs in the sub-acute and painful stage. In this group passive movement is worse than useless, and the surgeon should direct his energies to guard against ankylosis in a faulty position. If mobility is secured for the joint it is due to arrest of absorption by the removal of foci or an antidotal vaccine, and not to any surgical procedure. In the degenerative type, by removing trauma and friction, the disease is often arrested and improved. This is especially evident in the knee-joint, whose movements can always be kept under control. One frequently sees a rheumatoid knee in a middle-aged woman with slight limitation of movement and pain when the knee is extended. There is flexion deformity to a limited degree. The joint is blocked to extension by thickened synovial and other intra-articular structures, which are compressed and irritated by pressure from walking. The application of a cage allowing free movement in the painless range, but locked against the trauma of extension, often gives instant relief and checks the progress of disease.

There is no time to more than mention the treatment of the fixed deformities which are seen far too commonly. If hips and knees are flexed up to fifty or sixty degrees they can generally be extended by mechanical means. If the tibia is subluxated in addition, combined traction anteriorly and in the line of deformity should be employed. If the angle of flexion is greater the question of a wedge osteotomy through the knees should be considered. If adduction is added to flexion of the hips, a wedge osteotomy through the trochanter and a division of the adductors may be indicated. In complete ankylosis of both hips a pseudarthrosis of the one and an osteotomy of the other will suffice. No operation should be performed in the painful progressive stage of the proliferative type unless it is one devised to obliterate the joint. Operations upon the knee are frequently required. If the joint is thickened around the post-patellar pads and effusions recur, removal of all masses, including the synovial membrane in front of the joint, will often result in an increased range of painless movement. Complete synovectomies are sometimes needed where painful effusions and villous synovial membrane are diagnosed. No case is without the hope of improvement. Where there are several degrees of early movement in a joint the movement can be preserved by an osteotomy designed to transfer the limb to a useful position. If the flexion is marked I have removed a wedge from the tibia and divided the femur just above the joint, and by this means have secured a straight limb retaining the movement that already existed in the joint. Seventeen years ago I operated upon a young man of 25, who had acute flexion of both knees and hips, one hip being abducted and the other adducted, of several years' duration. The operation consisted of pseudarthrosis of one hip, trans-trochanteric osteotomy of the other, and excision of both knees. He was alive ten years later, and could walk a considerable distance with the aid of one stick. Surgeons, therefore, can do a great deal with the apparently derelict but surgery would not be needed if early preventive treatment were employed. I would utter one word of warning against endeavouring to straighten, by mechanical means, extreme flexion of the hip in elderly people. It is dangerous to life. I make no attempt to discuss the various physiotherapeutic methods—many of them useful, I desire most of all to urge early preventive methods.

of cases sent in as rheumatoid are always under treatment, an attempt is often made to segregate the cases with obvious infective clinical indications from the remainder, which persist under the non-committal term "rheumatoid." But the term "infective" is used in a special sense, the best known infective arthritides (tuberculous, gonococcal, syphilitic, suppurative, and acute rheumatic) being tacitly excluded. Having published in 1923 100 blood counts of chronic multiarticular arthritis of symmetrical type without distinction between rheumatoid and infective, it recently occurred to me to compare the blood pictures of a sufficient number of cases segregated in the hospital diagnoses as "infective" with those remaining as "rheumatoid." Reviewing in this way 171 cases, 32 of which are termed "infective" and 139 passed as "rheumatoid," the following comparison of chief points in the blood pictures is arrived at.

	Percentage of Rheumatoids	Percentage of Infectives	Percentage of Total Number
Normal leucocyte count (7 500 to 9 000)	15	9	14
Leucocytosis (9 000 and over)	54	72	57
Leucopenia (under 7 500)	31	19	23
Lymphocytes over 30 per cent	55	55	56
Lymphocytes under 20 per cent	3	6	3½
Reds over 5 000 000	34	47	36

Excepting one case (a child of 2 with leucocyte count of 96 000) the degree of leucocytosis ranged in both classes from 9,000 to 20,000, and of leucopenia 7,500 to 2,560.

Lymphocytes under normal figures are almost absent from both classes, but a considerable relative increase in lymphocytes is common to both. Thus the great majority of "rheumatoid" and "infective" counts differ from normal, the deviations are of the same kind and not markedly different in degree, all the cases show secondary anaemia, and about a third a moderate increase in reds. At first it was thought the leucocytoses might indicate coccal and the leucopenias bacillary infections, but some demonstrated coccal infections showed leucopenia, and Gordby, as Sir H. Rolleston notes, considers it a mark of streptococcal arthritis arising from oral sepsis. But we must not lose sight of the fact that 57 per cent of all the counts show leucocytosis.

Osteoarthritis, spondylitis, and fibrositis are excluded from the above review, but notwithstanding that a bacterial focus or origin is even less apparent in these cases than in rheumatoids their blood counts show a larger proportion of leucocytoses. Dr. Thomson, our house-physician, in his recent M.D. thesis shows that in 24 out of 25 cases of osteoarthritis and spondylitis investigated by him, marked leucocytosis and erythrocytosis are features, and incidentally that four cases only were definitely positive to complement fixation tests with gonococcal antigen.

As the blood picture by itself indicates general infection in 85 per cent of cases passed as rheumatoid, systematic serological tests appear to be the most likely means of identifying the causative organism, whether obtained from the rarely successful blood cultures and joint fluid examinations, or selected from the pathogenic flora of tonsils, teeth, urine, faeces, os uteri, etc., even the cases where these searches have drawn blank may furnish a positive serological result, pointing to one of the common classes of infective organisms, if suitable antigens are employed in the trials. Complement fixation and agglutination tests have been employed to this end, and precipitation tests will probably have their turn soon.

The streptococci commonly found in infections of tooth sockets, tonsils, and throat have been cultivated and used as antigens by several observers, amongst whom Richards has obtained results suggesting that *Streptococcus viridans* is almost a specific organism in arthritis from oral sepsis. He found no organism but this in 14 successful blood cultures from 104 cases in which he found streptococcal foci, the same organism only in 4 successful out of 54 joint fluid cultures, and with a mixed antigen from strains thus

VI—J. M. H. MUNRO, D.Sc., M.R.C.S., L.R.C.P.,
Honorary Pathologist Royal Mineral Water Hospital Bath

THAT rheumatoid arthritis is sometimes of infective origin was a moot point about a generation ago now we ask, with the opening paper, "Is it always infective?" In the Royal Mineral Water Hospital here, where numbers

grown he obtained positive complement fixation with the blood serum of 68 of the 104 cases.

I do not think results obtained on this side will bear out so exclusive an infection. The carbohydrate reactions of *S. viridans* are not given but Dr Melvin Gordon and other authorities believe it to be identical with *S. salinarum*, and 90 per cent of Richards's cultures were obtained from teeth or tonsils. To Dr M. Gordon and Dr Stone I am indebted for a satisfactory complement fixation technique with streptococcal antigens, with which I have carried out tests on 102 serums—71 arthritic and 31 non-arthritic—all designated by numbers, the results being compared with the diagnoses only after completion of the tests. When 3 minimal haemolytic doses of complement are used very few serums show fixation, but with 2 minimal haemolytic doses and $1\frac{1}{2}$ minimal haemolytic doses the majority of the rheumatoid, osteoarthritic, and fibrositic cases showed fixation, rigid controls, of course, being put up against each test. The antigen used was Dreyer's double streptococcal vaccine as supplied me by the Standards Laboratory at Oxford. This was prepared by extracting with formalin and acetone three cultures of streptococci, *S. salinarum* not being included, and one, if not two, being haemolytic. Some serums of undoubted rheumatoid and osteoarthritic patients were negative, and so were the majority of the non-arthritic control serums. One or two pyorrhoeic patients not suffering from arthritis gave fixation, on the other hand, twelve serums from healthy persons with gums and teeth in good order were all negative. Evidence like this lends support to the streptococcal infection theory, but there are many difficulties in making such tests conclusively diagnostic. Moreover, Gordon, whose classification I follow for convenience, has himself shown the specificity as regards complement fixation and agglutination of many strains in the *salinarum* and *faecalis* groups, and Dr Stone has found a certain amount of cross-fixation with strains from different groups. In a case I described to the Clinical Society of Bath last January staphylococci and *Streptococcus pyogenes* were found infecting the sockets of every one of the sixteen teeth not previously extracted, and on extracting these teeth in batches of two or three every root tip gave smears abounding with streptococci only, notwithstanding that they had been twice skilgraphed and pronounced sound by two skilgraphers and two dentists. This patient's blood gave positive fixation with an antigen of the streptococcus, not with one of the staphylococcus. There was no abscess or microscopic pus in any of these sixteen tooth sockets (though there had been in some of those previously removed), and having only a film of streptococci and leucocytes to deal with in cases like these one wonders whether the demonstrated haemo-bactericidal power of ultra-violet radiation could be employed both locally and generally with any success in saving such teeth, avoiding flucy after extraction, and raising the power of the tissues to react to vaccines.

Having found *Staphylococcus epidermidis* in blood cultures and smears from joint effusions in more than one case of "rheumatoid," I feel inclined, instead of expecting a specific organism for this disease, to suspect the Gram-positive cocci generally for the majority of cases—staphylococci, streptococci, and pneumococci. All these we know outside of arthritis to be responsible for chronic as well as acute infections.

Brilliant rheumitoids are almost uninvestigated and are probably rare. Finding they might explain the greater incidence of rheumatoids in females I sought to confirm blood infection by agglutination tests in some scores of cases in which *B. coli* was suspected, but there was no mixed coloration.

Coincident tuberculous activity in our rheumatoid cases is common if skin reactions to a small dose of old tuberculin be accepted as evidence. 50 per cent of positives are found. Wassermann tests (3 minimal haemolytic doses complement) are positive in a much smaller proportion. Possibly some of the leucopemias are thus caused.

Although I have known more than one arthritis case diagnosed as "rheumatoid" subsequently proved to be tuberculous, I regard the great majority of the above

cases as having tuberculosis antecedently or as an added infection to the arthritic one. But I do not think there is any evidence of surgical or pulmonary tuberculosis increasing susceptibility to rheumatoid arthritis.

VII—A. G. TIMBRILL FISHLR, M.C., F.R.C.S.,

Late Hunterian Professor, Royal College of Surgeons
 Consulting Surgeon, Ministry of Pensions, etc.

It is to be hoped that further research will ere long justify us in replacing the terms "rheumatoid arthritis" and "osteoarthritis" by a more satisfactory and scientific nomenclature. They are not infrequently used as a cloak of ignorance, and the term "rheumatoid arthritis" is a pseudo-clinical term in which the disease is compared to another, the etiology of which is still undecided. Most of the present classifications are unsatisfactory and confusing in that clinical, pathological, and anatomical classifications are jumbled together. It is suggested that the term "chronic arthritis" is simple and accurate, and embraces all the pathological types. It allows also for expression. For instance, as the clinicians, bacteriologists, and possibly the chemical pathologists gradually differentiate the various etiological types, the causation factor can be added thereto and the type of chronic arthritis thus indicated. This is an ideal which can only be accomplished by research and co-operation and a combined attack upon the problem.

Pathological Types of Chronic Arthritis

Classification—I venture to suggest the following classification of the pathological types of chronic arthritis is being simple and based upon the principal anatomical site of the joint changes. There are three principal groups.

Group 1—This group, which I have called "chronic arthritis of the chondro-osseous type," corresponds to the condition sometimes known as osteoarthritis, or the degenerative type of Nichols and Richardson. The first change consists in a degeneration of the central area of the articular cartilage. The changes that follow are in a sense all consequent upon this primary degeneration—although they themselves are more inflammatory than degenerative. For instance, the lateral part of the cartilage proliferates, and osteophytes are formed to extend the articular area. The subchondral layer of bone becomes sclerosed, hardened and enbated in an endeavour to form a new joint surface and thus compensate for the loss of the central portions of the cartilage. The changes in the synovial membrane are at first insignificant. There is villous hypertrophy and increased vascularity of the synovial fringe near the articular margins. Later, however, the membrane and capsule become thickened and fibrous, and arterio-sclerotic changes may then be seen therein. It is clear, however, that these occur concurrently, and are not of etiological importance.

The histological changes in the membrane and capsule are of the nature of an inflammatory hyperplasia, and an important point is that collections of small cell infiltration which are frequent in the next two groups, are usually absent. These changes are frequently seen *post mortem* in the joints of persons past the meridian of life and are encountered as the result of trivial or long-continued intra-articular irritation. It is the type to which the term "degenerative" may be logically applied, as this is at any rate the primary change, and the subsequent changes appear to be consequential. Long continued toxic states may bring about such degeneration, but the pathological changes are not such as we usually associate with a localized infection.

Group 2—In the second great pathological group which may be called "chronic arthritis of the mixed type," the synovial membrane and the articular surface are both involved simultaneously, and the changes proceed concurrently although the process starts in the membrane. The central part of the articular cartilage is destroyed by toxins in the synovial fluid, and its surface invaded by

an advancing tide of pannus from the membrane, while it is simultaneously invaded from beneath by outgrowths of vascular connective tissue from the underlying bone.

There is evidence of chronic inflammatory changes in the membrane—the villi of which enlarge and multiply, and in some cases cartilage or bone may develop therein. Veritable little tumours may be formed, and I have produced these experimentally in animals. Histologically there is well marked evidence of chronic or subacute inflammation in the form of rounded foci of small-celled infiltration, and the appearances are such as we associate with an infective process.

According to the cause and stage of the inflammatory process the condition is apt to lead to partial or complete ankylosis, especially if prolonged rest is ordered. In the more chronic types where movement is permitted, lipping of the articular margins is a prominent feature, and may be compensatory, as in the first group. Elimination may also occur in the later stages, and a condition results which at first sight somewhat resembles our first group.

Group 3.—In the third group, which we may call "chronic arthritis of the synovial type," the inflammatory process remains for a considerable period, principally localized in the synovial membrane and capsule. Slight degenerative changes after a while occur in the central part of the articular cartilage, and a little pannus may stray for a short distance over the articular surface and slight lipping may occur. The outstanding feature of the pathological picture is, however, the inflammatory changes in the synovial membrane. Here again fat, cartilage, or bone may form therein.

Groups 2 and 3 constitute the condition usually known as "rheumatoid arthritis" or the "proliferative type" of Nichols and Richardson.

Physiology of Joints

At first sight the pathology appears complicated, but this has been largely due to our ignorance of the physiology of joints.

A few years ago I endeavoured to establish the principle that the remarkable difference in the behaviour of the central and lateral portions of the articular surface—the degeneration of the former and the proliferation of the latter—is due to a difference in their mode of nutrition, and that the lateral portion of the cartilage derives an additional source of nutrition from the circulus articularis vasculosus.

These physiological facts are not of mere academic interest as explaining the nature and significance of the pathological changes, but are of great practical importance. A study of the physiology of joints convinces one of the great adaptability of the joint structures, and how in the more chronic types Nature is striving hard to repair the damage and to prepare the joint for renewed function. How frequently, instead of assisting, the medical man actually impedes this process by an imperfect knowledge of physiological principles and a too rigid application of the doctrines of rest and splintage.

Practical Applications

What lessons do these pathological and physiological facts teach with regard to treatment?

In the more acute forms deformity is to be religiously avoided by the measures that Sir Robert Jones has indicated, and we must aim at the ideal of a movable joint wherever feasible by the institution of early movements.

In the more chronic forms regular movements through complete ranges are instituted from the first, whereby we help Nature's efforts to repair the damage inflicted upon the joints and the following benefits result:

- 1 Contracture by scar tissue, both intra- and extra-articular, with resulting limitation of movement, is prevented.
- 2 Mechanical obstruction by osteophytes cannot occur.
- 3 The process of ossification is materially assisted.
- 4 Muscle tone is preserved.

When, however, such a joint is fixed it is physiologically placed at the greatest disadvantage to combat infection or toxic onslaught, for the circulation, not only of lymph but

of blood, and the secretion and absorption of synovial fluid, depend upon regular movements. The immense importance of these local measures is often entirely overlooked.

When the principles have been neglected deformity must be treated by appropriate surgical measures. There is an unfortunate lack of co-operation in some of these cases and experience teaches that cases in which the disease is no longer active are often treated by various medical measures, which cases in reality urgently require surgical treatment. It is sometimes forgotten that one cannot disperse a joint full of loose bodies by administering vaccines, neither will all the drugs in the *Pharmacopoeia* have any appreciable effect upon a firm ankylosis in faulty position.

I do not propose to discuss etiology beyond stating that in my experience attempts to isolate or grow organisms from tissues removed at operation from the joints have been usually negative even in the last two groups. The pathological changes, however, seem to point to an infective agent, and I believe that in addition to the cases associated with some obvious toxic focus there is a large group in which such foci are absent, probably due to a filter passing virus. The pathological anatomy of chronic arthritis can yield but few further secrets. The stage is now set for the bacteriologist and chemical pathologist armed with the most modern technical methods, to find it last the final solution of this most complicated problem.

VIII.—SIR WILLIAM WILLCOX, K C I E, C B, C M G; M D F R C P

Physician to St Mary's Hospital London

Many factors play a part in the etiology of rheumatoid arthritis, but a careful consideration of these leads inevitably to the conclusion that "infection" must be regarded as the primary cause in the great majority of cases.

It must be clearly understood that by "rheumatoid arthritis" is meant a pathological condition of the affected joints showing definite changes of the chronic inflammatory nature peculiar to the condition.

Thus "intermittent hydrarthrosis," the remarkable transitory effusion into joints occurring with a definite periodicity, is an example of a condition of sensitization to some toxin in the body, the reaction to which is manifested by synovial joint effusion. It is akin to allergic anaphylaxis, asthma, etc., in its pathology, and is not to be regarded as rheumatoid arthritis, for the characteristic morbid anatomical joint changes are absent.

For similar reasons true gout should be excluded, for there is a consensus of opinion that this also is an example of an idiosyncratic sensibility to some toxin in the body.

Neuropathic joint lesions such as those occurring in the dorsals (Charcot's atrophy) are readily distinguishable from true rheumatoid arthritis by their clinical symptoms as well as by the morbid joint changes and must be excluded from consideration.

With these reservations the claim for the infective origin of rheumatoid arthritis is exceedingly strong and must be admitted. The following reasons appear to me to be of great importance:

1 Many well known pathological organisms give rise to arthritis which is indistinguishable from rheumatoid arthritis. Gonococcal infection forms one of the best known examples, but others may be cited, such as those of bacillary dysentery, pneumococcal infection, and typhoid and paratyphoid fever. Then, again streptococcal septicaemia, in which the organism has been obtained from the blood stream, is not infrequently accompanied by a multiple arthritis. On two occasions in my wards at St Mary's Hospital a typical multiple arthritis indistinguishable from rheumatoid arthritis has developed in hospital after an acute streptococcal tonsillitis. In these cases the joint condition was clearly not one of acute or subacute rheumatism but a true arthritis which responded in no way to treatment by salicylates.

2 The well known frequency of occurrence of a progressive "rheumatoid arthritis" following parturition is strongly suggestive of an infective origin.

3 The great majority of cases of "rheumatoid arthritis" show evidence of an infective cause. Often when a case is seen for the first time in an advanced stage of the disease it is difficult to state precisely the original focus of infection, for this may have been removed previously. Cases seen within the first few months of their origin, in my experience, show almost always some definite infective origin.

4 Removal of infective foci is commonly followed by improvement of the disease. Careful search must be made for dental sepsis, both by expert clinical examination and by radiography. The importance of apical dental infection in cases where the gums appear healthy on macroscopic examination is now well recognized. Dead teeth act in some cases as foci of infection, if the disease persists and no other obvious focus is present dead teeth should be removed. In a discussion at the Royal Society of Medicine on dental sepsis as an etiological factor in disease of the organs, in 1923, I quoted the infective origin of 100 consecutive cases of arthritis and fibrositis under my care. The figures were

Dental sepsis	72
Intestinal	13
Tonsillar	10
Urethral (gonococcal)	5

1 Of the cases of dental sepsis, 15 out of the 72 showed definite apical infection. These figures must be taken as giving only an approximate idea of the infective origin.

To obtain an accurate idea of the true infective origin of rheumatoid arthritis it would be necessary to collate a very large number of cases the etiological investigation of which had been carried out in the early stages of the disease. In consideration of whether the teeth are the cause of infection, very careful consideration must be given to each individual case—for example, in some cases a slight amount of change shown by radiography may be responsible for the acute symptoms of severe arthritis.

The tonsils are not infrequently a focus of infection, and I should like to lay stress on the fact that the tonsillar origin of rheumatoid arthritis is often shown by the tendency for the joint symptoms to show marked improvement and often disappearance, and then to be followed by recurrences of the arthritis. The tonsillar cases are more often seen in young people, they are more likely to be associated with pyrexial periods, and there is usually a greater tendency for effusion into the joints.

The septic stumps of tonsils which have previously been partially removed are not infrequently the cause of rheumatoid arthritis. The existence of enlarged tonsillar glands is an important clinical indication, and the necessity for an examination by an expert rhinologist is called for in such cases.

The nasal accessory sinuses have been found by me in a number of obscure cases to be the primary focus of infection. Most commonly the maxillary antra are the site of infection. In some cases these had been infected from a molar tooth, in others the infection appeared to have been from the nasal cavity. Attention should be called to the difficulty of diagnosis of nasal infection. Radiography and transillumination are not infrequently misleading, and the only certain test in doubtful cases is that of antral puncture and bacteriological examination of the antral washings. In several cases under my care where an antral infection has been found, and drainage of the infected antrum effected the active inflammation of the joints has subsided and marked improvement followed.

Intestinal Infection

The colon is most commonly implicated, the tubular glands being no doubt the site of infection. In cases where the primary focus of infection is in the mouth or nasopharynx it cannot be long before the intestinal glands become infected, and these frequently carry on the infective process even when the primary focus has been eradicated. Sir Arthur Keith has called attention to the important influence which the tubular glands have on the general metabolic processes.

In elderly patients the intestinal infection is often the primary focus. For the last five years, in all cases under

my care at St Mary's Hospital, a careful bacteriological examination has been made of the colon washings, and in over 90 per cent of these cases a definite pathogenic infection, usually of the *Streptococcus viridans* type, has been found. The signs of active colitis in cases of rheumatoid arthritis showing colon infection are usually absent, but the colon washings generally reveal evidence of mucus.

Dysenteritis has been found in a few of my cases to be the focus of infection in arthritis of the rheumatoid type. Its presence is revealed by x-ray examination.

Urethral examination is advisable if there is a history or actual evidence of any urethral infection. Bacteriological examination of the urine, especially after prostatic massage in males, may show evidence of the infective origin.

Examination of the pelvic organs in women is important, and a swab of the cervical discharge should be bacteriologically examined. A latent chronic salpingitis has been found in a few cases to be the cause of rheumatoid arthritis. In my experience, excluding gonococcal cases, urogenital causes of arthritis are rare.

The eradication of the primary focus of infection in early cases of rheumatoid arthritis has, in my experience, usually been followed by a cessation of the active inflammatory changes in the infected joints. Where bony changes have occurred, or other disorganization of the joint structures, it cannot be expected that removal of focal infection will rectify these. When the active inflammation of a damaged joint has ceased, treatment for the restoration of movement will be followed by real improvement.

5 "Gout" has been excluded as being always infective in origin. It must be mentioned, however, that many cases of rheumatoid arthritis show some association with gout, and these were included in the old term "rheumatic gout." I believe that in these borderline cases some infection always exists and this is commonly intestinal. Similarly some cases with a definite history of acute rheumatism in early life develop later rheumatoid arthritis. The two conditions are distinct, but the same diathesis obtains in each.

6 The presence of an infective cause in rheumatoid arthritis is shown by many other manifestations of the causal toxæmia, such as secondary anaemia, debility, malnutrition, gastric or duodenal ulcer, colitis, chronic appendicitis, cholecystitis, skin affections, etc.

I would go so far as to say that rheumatoid arthritis is not a disease *per se*, but it is the joint manifestation of a chronic toxæmia. The toxæmia is usually due to an infection with a streptococcus of mild virulence, such as one of the *viridans* group, and very commonly the toxæmia originates in a primary focus of infection in which the causal organisms are aggregated.

Attention should be directed to the difference between acute rheumatoid arthritis and the purely chronic type. In the former, though the joint manifestations are very acute yet the joint changes frequently completely clear up.

Tuberculosis elsewhere is not in my experience, an important etiological factor. Tuberculous arthritis is readily distinguishable clinically and by radiographic examination from rheumatoid arthritis, and there should be no confusion between the conditions. Dr Wingfield has called attention to the great importance of focal infections as a predisposing cause of pulmonary tuberculosis. It is obvious that in cases of pulmonary tuberculosis with an existing focal infection of streptococcal origin, there is a likelihood of arthritis developing, and the coexistence of these two conditions is an adequate explanation of the association of tuberculosis with chronic arthritis.

"Constitution" or "diathesis" is, I believe, an important etiological factor. Thus an inherited tendency exists in some families for joint trouble in others for the development of gastric or duodenal ulcer, then again a tendency to the development of pernicious anaemia, or diabetes may be inherited.

If a chronic infection of streptococcal origin occurs in an individual the inherited diathesis or constitution may determine the part of the body which will bear the brunt of the damage.

Disorders of metabolism may determine to some extent the type of arthritis which develops—for example, the so called "rheumatic gout"—but the investigations made on cases have failed to show the constant presence of any special metabolic disorder.

Arthritis and endocrine disorders are both commonly due to the same cause—namely, infection. There is strong evidence that diabetes is, in its early stages, caused in a large percentage of cases by a chronic toxæmia, such as obtains in rheumatoid arthritis (*Practitioner*, December, 1923 "The treatment of diabetes"), and I have seen several early cases of exophthalmic goitre in which focal infection was an obvious causal factor.

For these reasons it seems clear that arthritis and endocrine disorders, when coexistent, are both due to a common cause—namely, infection.

TREATMENT OF ARTHRITIS

Rheumatoid arthritis is the gauge of the immunity of the patient to some chronic infection, by constant dosage with toxins the joint disease is lit up and the inflammatory condition progresses. The treatment should aim at the removal as far as possible of the infective cause, and in stimulating by any means available the body immunity.

Careful search for, and eradication, as far as possible, of, any focus of infection, is the first step. Since colon infection is present in most cases, colon lavage is of value, especially in cases of long standing. Plombières colon irrigations, using a warm solution of 1 drachm of salt and 1 drachm of sodium bicarbonate to the pint, can be satisfactorily given by any trained nurse. The patient should lie on the left side and about 1½ to 2 pints of the solution be slowly introduced by means of a funnel with rectal tube attached, at a pressure of about 1 foot. The tube need only be passed two or three inches beyond the anal orifice. After the liquid has been retained a few minutes it is evacuated, and a second lavage similarly repeated. These treatments may be given with advantage on alternate days for the first week, and afterwards twice weekly for three or four weeks. Intestinal antiseptics such as guaiacol carbonate and salol are of value. Tincture of iodine (French *Pharmacopœia* without potassium iodide), commencing with three or four minims in a wineglassful of milk or water three times a day, appears to do good. This probably acts by stimulating the thyroid function.

Local treatment of the joints by iodine poultices, hot applications, radiant heat, ionization, or diathermy, is helpful.

Massage and active and passive movements of the joints are only indicated when the active inflammation has completely subsided.

Stimulation of the general immunity of the body by means of artificial sunlight, or carefully regulated sun baths, is of value.

The diet should be of high nutritive value and rich in vitamin containing foods, alcohol is best avoided. In some cases endocrine therapy, such as small doses of thyroid gland or parathyroid, may be helpful.

Protein shock therapy, such as injections of peptone solution or of typhoid vaccine, has, in my experience, been disappointing. In some cases a definite temporary improvement has occurred, but this has usually been followed by a relapse to the former condition.

Vaccine Therapy

This should never be used until the focus of infection has been removed as far as possible. Vaccine therapy may then supplement the other methods of treatment. Autogenous vaccines made from the organism believed to be causing the toxæmia are isolated from the infected teeth or other primary focus and from the colon washings.

It is very important that overdosage be avoided. It is best to commence with a weak vaccine of strength 5 million per cubic centimetre and to give an initial dose of 2 minims increasing by 1 or 2 minims every five days for six doses, and afterwards giving weekly doses of gradually increasing strength. A vaccine of strength 50 million per cubic centimetre may be used later if benefit results.

IX—A CAWADIAS, M D, M R C P,

Professor of Medicine, University of Athens

An important contribution to the discussion on rheumatoid arthritis is given by the researches on sulphur metabolism. As time represents the most important way of elimination of sulphur, urinary determinations give us the key to sulphur metabolic troubles. I have made a certain number of such determinations, of which a part has been published in a note read before the French Academy of Medicine.

The first thing these determinations show us is that there is an excess of total sulphur eliminated in these patients. Instead of the normal 250 to 300 grams (expressed in SO_2) per diem, we find 4 and 5 grams of total sulphur in the urine of rheumatic patients. This sulphur is not due to a special diet. We know that in general diet has no influence on the quantity of urinary sulphur, notwithstanding that we have made comparative determinations in non rheumatic patients following the same diet as our rheumatic patients, and we found no excess of urinary sulphur in them. This sulphur, on the other hand, is not simply a sign of increased protein destruction. If that were the case there would be a parallel rotatory, and the ratio of nitrogen to sulphur would be normal as 5:1. But in our cases the loss in nitrogen was not parallel to that in sulphur.

We are induced, therefore, to admit that this sulphur demineralization is a special metabolic trouble in rheumatoid arthritis—in other words, that the tissues of the rheumatic patient have lost the power of retaining sulphur, in the same manner as the tissues of the tuberculous have lost the ability to retain calcium, and even the tissues of the diabetic to retain carbohydrate.

The second point in our sulphur determinations consists in the relative increase of the neutral or imperfectly oxidized sulphur. Whereas normally this neutral sulphur represents 14 to 20 per cent of the total urinary sulphur, we find in our cases 25 and 33 per cent.

This relative predominance of neutral sulphur can be explained by a general deficiency in the oxidation processes of the organism. It is interesting to remember the researches of O. Loewi in animals intoxicated by hydrocyanic acid, in whose urine this author found up to 54 per cent of neutral sulphur. Now hydrocyanic acid determines an internal asphyxia—that is, it makes the protoplasm lose its affinity for oxygen.

Lastly, it is important to remark that in rheumatoid arthritis the ethereal sulphates are not increased. In the absence of intestinal fermentation an increase of these sulphates in the urine of rheumatic patients would indicate a destruction of cartilage, because chondroitin sulphuric acid is an ethereal sulphuric acid of chondroitin, and is eliminated as an ethereal sulphate. The fact that these ethereal sulphates are not increased shows that the excess of sulphur elimination does not point to a destruction of cartilage, but to a general cellular metabolic trouble.

We find, therefore, in studying the sulphur metabolism in rheumatoid arthritis two syndromes: (a) syndrome of sulphur demineralization, (b) syndrome of sulphur hypo-oxidation. This last is probably part of a general syndrome of inefficiency of organic oxidations—Bouchard's "ralentissement de la nutrition", the sulphur demineralization is more specific for rheumatoid arthritis.

These facts help us to understand the therapeutic action of sulphur. After injections of colloidal sulphur this sulphur demineralization is often checked, as we have seen in cases published in an article in the *Journal des Praticiens*. On the other hand, they give us an insight into the nature of rheumatoid arthritis. Of course, these metabolic troubles must be first considered as a result of the infection—or intoxication—which causes the disease. But it is not illogical to think that a certain predisposition towards hypo-oxidation and towards sulphur demineralization exists beforehand, hereditarily and constitutionally, and that it helps the development of the disease.

Many eminent clinicians represent the disease G as the result of the action of an external cause W on a reacting organism R . $G=W/R$. In rheumatoid arthritis W represents the infective agent, R the predisposing organism. The two elements are absolutely necessary for the determination

of the disease. But we think that R plays a greater part, and that without a certain metabolic type—a certain 'humoral' type, to use a Hippocratic expression—the micro-organism W, inoffensive probably in other individuals, cannot determine the disease.

GENERAL DISCUSSION

Sir JAMES BARR (Liverpool) said that in 1913 he gave an address at Sunderland on rheumatoid arthritis which excited a good deal of controversy in the *BRITISH MEDICAL JOURNAL*. The views which he then expressed he had consistently held and persisted over since—namely, that true rheumatoid arthritis was due to a prolonged mild acidosis which decalcified the synovial membrane and fibrous tissue of the joints, and finally attacked the cartilages and bony structures. The popular idea was that the disease was microbial or toxic in origin, and all known organisms had been called into requisition to explain different cases, but no specific organism had been discovered. Whatever the cause of the acidosis, the immediate cause of the mischief was the decalcification. In all these cases there was defective vagotonia, the stomach was dilated, whether distended or not, with acid fermentation of its contents. There was no hyperchlorhydria, though the amount of free hydrochloric acid was not necessarily below normal. The amount of free hydrochloric acid was not sufficient to arrest the acid fermentation and formation of organic acids, although the blood never became acid, these acids were sufficient to lessen the buffer salts in the blood and attack the fixed calcium in the tissues. There were many acid-forming organisms in the stomach where the stasis was. Any stasis in the bowel might give rise to intestinal putrefaction, but the *Bacillus coli* flourished in an alkaline medium and was not a causative agent of rheumatoid arthritis. In these cases there was increased basal metabolism, and very few of them could hold their breath for thirty seconds. The pulse was frequent, the blood pressure low, and perspiration occurred readily. Overaction of the ovaries and thyroid would mischief by increasing calcium metabolism. Any of his audience could bring on pains in their joints by living on a carbohydrate diet and taking large quantities of citric, tartaric, acetic, or lactic acid, he would not advise them to carry the experiment too far for fear they might work mischief without the aid of a micro-organism. In his opinion there was no other chronic disease so amenable to treatment if taken early, say within the first six months, so long as the cartilages and bones were not involved the case was very hopeful. In this respect he sympathized with the spa physicians, because they chiefly had to treat

the derelicts of the medical profession. The cases which required the attention of a surgeon had been very badly handled. It might be thought that the decalcification would be very easily corrected by giving large amounts of soluble calcium salts, but no matter how much was given by the mouth only a small amount was absorbed, and the amount of calcium which the blood would hold was not sufficient to act as a buffer salt, it was therefore necessary to give also a liberal supply of sodium and potassium salts. The calcium passed into the lacteals is a soap, consequently it was necessary to form a soluble soap with unsaturated fatty acids such as olive oil. Stearin and palmitin formed very insoluble soaps which only irritated the bowel. Unnecessarily large doses of calcium were apt to lessen the motor function of the stomach, hence milk was not the best method of administering calcium, as it might cause undue retention and lead to acid fermentation, which would do mischief. The sour-milk cure in this disease had fizzled out long ago. The only endocrine glands of value were the parathyroid, pituitary, and suprarenal, which led to calcium retention. In a myxoedematous patient the development of rheumatoid arthritis must be a rare event, but osteoarthritis might readily occur. The best diet was red meat, and, as Dr Woods Hutchinson had said, plenty of it, he had entered very fully into that question in 1913, and there was no need to repeat what he had then said. A good plan was to take a glass or two of hot water three hours after meals and then elicit the stomach reflex, which relaxed the pylorus and allowed the stomach to empty itself. This should always be done at bedtime and be followed by two tablespoonfuls of olive oil.

The PRESIDENT (Lord Dawson), in closing the discussion, said that it seemed clear that infection played a part in the etiology—the question was, what part? It was often difficult to decide the balance of advantage and disadvantage in removing septic foci. In some cases the infection might be in some part so difficult of access as to make even its detection impossible, and in others it might well be that lack of resistance allowed an ordinarily harmless organism to become pathogenic. In investigating the factor of low resistance the clinician looked for co-operation with the biochemist, and Professor Cawdron's observations were very suggestive on this point. With regard to the extraction of teeth, he looked upon ago as a contraindication to any extensive removal, and the results of extraction were often very disappointing, but even so some comfort might be derived from the fact that the care now given to the teeth had undoubtedly produced a great improvement in the general health of the people.

THE SURGICAL TREATMENT OF MITRAL STENOSIS

BY

H. S. SOUTTAR, CBE, MCh, FRCS,
SURGEON (WITH CARE OF OUT-PATIENTS) LONDON HOSPITAL

THERE can be no more fascinating problem in surgery than the relief of pathological conditions of the valves of the heart. Despite the consecutive changes to which these lesions may have given rise in the cardiac muscle, the relief of the lesions themselves would undoubtedly be of immense service to the patient and must be followed by marked improvement in his general condition. Expressed in these terms the problem is to a large extent mechanical, and as such should already be within the scope of surgery, were it not for the extraordinary nature of the conditions under which the problem must be attacked. We are however, of opinion that these conditions again are purely mechanical, and that apart from them the heart is as amenable to surgical treatment as any other organ. Incisions can be made into its chambers, portions of its structure can be excised, and internal manipulations can be carried out, without the slightest interference with its action, and there is ample evidence that wounds of the heart heal as readily as those in any other region.

The conditions which appear as fundamental are, first,

that the operations have to be carried out on a structure in rapid movement, and secondly, that no interference whatever with the circulation must take place. The first is not quite so difficult as it sounds, for it is possible to fix the actual portion of the heart which is under operation, but it must obviously limit the possibilities of repair. In animals the second condition may sometimes be ignored, and the circulation has been clamped for as much as two minutes. This, however, would never be justifiable in a human being, in view of the extreme danger to the brain from even the shortest check to its blood supply. Any manipulations which are carried out must therefore be executed in the full flow of the blood stream, and they must not perceptibly interfere with the contractions of the heart.

The simplest valvular lesion for surgical interference is stenosis of one of the valves, and of these the mitral valve is perhaps the most accessible. I have been interested for some time in the development of a suitable technique for reaching this valve, and I owe to Dr Otto Lewton the opportunity presented by the following case for putting my ideas to the test. A description of the case itself will give the clearest indication of the method of approach I adopted and of the technique which I devised.

Decription of Case

L. H. aged 15 was admitted to the London Hospital in January 1921 suffering from chorea and mitral stenosis. Her subsequent history was one of many relapses, with steadily

increasing failure of compensation. In September, 1924, she was admitted with haemoptysis, vomiting, and severe dyspnoea. She was cyanosed, her feet were swollen, and her liver was enlarged and tender. After three weeks in hospital she had greatly improved and was sent to a convalescent home, whence three weeks later she was discharged.

Early in March, 1925, she appeared at the London Hospital with cough, dyspnoea, and pain in the limbs. She was sent home to bed and given digitalis and aspirin, but she did not improve. After a severe attack of epistaxis and precordial pain she was again admitted as an inpatient.

She was a thin girl with a bright malar flush. Her pulse rate was 128, and respirations 32. Cardiac pulsation was visible over a large area of the left chest, and the rib cartilages in this area were very soft and had a forward bulge. The apex beat was in the fifth space, outside the mid clavicular line, and the area of cardiac dullness extended to the second space above. In the mitral area there was a long rumbling diastolic murmur, followed by a soft blowing systolic murmur, the latter being conducted out into the axilla. A presystolic murmur was present, but was not very marked. The liver was not obviously enlarged, but was slightly tender on palpation.

After a week's rest in bed her pulse fell to 80 and her respirations to 24, while her general condition greatly improved. Her pulse was now small but perfectly regular, with a systolic pressure of 95 mm. There was no presystolic murmur or thrill but a long diastolic murmur of low pitch was followed by a soft blowing systolic murmur.

In view of her many relapses it appeared that her heart was unable to establish compensation for the combined stenosis and regurgitation from which she suffered, and it was therefore decided to attempt to relieve the stenosis by surgical means.

Operation

On May 6th, 1925 under intratracheal anaesthesia, a curved incision was made along the fourth left intercostal space, up along the middle of the sternum, and outwards along the first left intercostal space. The skin and subcutaneous tissues, with the left breast, were turned outwards, exposing an area of the chest wall about five inches square. On the outer side of this area a short horizontal incision was made along each of the three ribs exposed (Fig 1), and through these incisions the ribs

FIG 1—Skin and subcutaneous tissue reflected with ribs exposed prior to division.

were in turn divided. The chest wall was now divided a little within the line of the original incision by cutting through the muscles and costal cartilages and the flap so formed was turned outwards, the pleura being included in the flap (Fig 2).

A very full exposure of the left side of the pericardium was thus obtained, while with an intratracheal pressure of 15 mm Hg there was only moderate collapse of the left lung. The action of the heart now became extremely hurried, the pulse rising to 150, and it was evident that until it settled down nothing further could be attempted. After five minutes delay the beats became slower and steadier and it was decided that we could safely proceed. The pericardium was opened by a vertical incision three inches long in the centre of which the left auricular appendage came prominently forward (Fig 3). Two sutures were passed through the upper and lower margins of the appendage so that it could be readily drawn forward.

As the heart was still beating very rapidly the wound was covered with hot saline pads and a subcutaneous injection of 1/100 grain of strophantidin was given. After a delay of ten minutes the heart had steadied down to a rate of 120 and the blood pressure, which had fallen to 60 mm, had returned to 80 mm.

The auricular appendage was now drawn forward, a soft curved clamp (Fig 4) was applied to its base, and it was

FIG 4

incised in an anteroposterior direction with scissors (Fig 5). Into this opening the left forefinger was inserted (Fig 6), the

FIG 5

FIG 6

clamp was withdrawn, and the appendage was drawn over the finger like a glove by means of the sutures. The whole of the inside of the left auricle could now be explored with facility. It was immediately evident from the rush of blood against the finger that gross regurgitation was taking place, but there was not so much thickening of the valves as had been expected. The finger was pressed into the ventricle through the orifice of the mitral valve without encountering resistance, and the cusps of the valve could be easily felt and their condition estimated.

The finger was kept in the auricle for perhaps two minutes, and during that time, so long as it remained in the auricle, it appeared to produce no effect upon the heart beat or the pulse. The moment, however, that it passed into the orifice of the mitral valve the blood pressure fell to zero, although even then no change in the cardiac rhythm could be detected. The blood stream was simply cut off by the finger, which presumably just fitted the stenosed orifice. As, however, the stenosis was of such moderate degree, and was accompanied by so little thickening of the valves, it was decided not to carry out the valve section which had been arranged, but to limit intervention to such dilatation as could be carried out by the finger. It was felt that an actual section of the valve might only make matters worse by increasing the degree of regurgitation, while the breaking down of adhesions by the finger might improve the condition as regards both regurgitation and stenosis.

It was now decided to withdraw the finger and close the appendage. Unfortunately, at the critical moment of withdrawal the lower retaining suture cut through, the appendage slipped back into the pericardium and there was a sudden gush of blood, which, however, was instantly checked by pressing the appendage against the heart. With a little manipulation the tip of the appendage was now grasped between the finger and thumb, which held it securely closed while an assistant passed a silk ligature round it and tied it off. The pericardium was closed, and a certain amount of blood, which in this *contretemps* had escaped into the pleural cavity, was removed with moist gauze pads. The intratracheal pressure was raised so as to cause the left lung to expand, and the wound was closed in layers, the ribs being accurately sutured in position. Before the flap was actually closed a small quantity of 60 per cent alcohol was injected into the intercostal nerves just outside the point at which the ribs had been divided.

Immediately the chest was closed the heart's action returned to normal, and on the conclusion of the operation the general condition of the patient was indistinguishable from that at the beginning. She had a bright colour and an excellent pulse. Except at the moment when the suture cut out her condition had never caused the slightest anxiety, and even then there was only a momentary drop in the blood pressure. The whole operation took precisely sixty minutes.

She made an uninterrupted recovery, the freedom from pain or any disturbance which might have been expected to result from the operation being remarkable. Her general condition appeared to be greatly improved, but the physical signs showed little or no change. She went to the convalescent and left in bed for six weeks, but as at the end of that time her pulse rate had remained constant at about 90 she was gradually

FIG 2—Ribs divided and flap formed by cutting through muscles and costal cartilages turned back left side of pericardium exposed

FIG 3—Vertical incision in pericardium exposing left auricular appendage

allowed to get up. At the end of three months he declared that she felt perfectly well, although she still became somewhat breathless on exertion.

REMARKS

I believe that this is the first occasion upon which an attempt has been made to reach the mitral valve by this route in the human being or to subject the interior of the heart to digital examination. The value of the method

cannot possibly be judged on a single case, but I think that I may claim to have shown that the method is practicable and that it is reasonably safe. Indeed, the features which most struck all who were present at the operation were the facility and the absolute safety of the whole procedure, while even on a first attempt the amount and precision of the information to be gained by digital exploration were very remarkable. I had intended to divide the aortic cusp

TABLE IV—Age Incidence of Aneurysm, Tabes Dorsalis, and General Paralysis

	Below 40	Below 50	Aged 50 years
Aneurysm	42.5 per cent	75.5 per cent	43.87 years
Tabes dorsalis	61.0	83.0	42.41
General paralysis of the insane	62.0	83.0	42.44

The average age at death in all three diseases is the same within a year or two—a fact which supports the view that they have a common origin.

Rupture as a Cause of Death in Aneurysm

The cause of death and the frequency of rupture as a cause is an interesting point about aortic aneurysm, and I published the *post mortem* experiences of the Manchester Royal Infirmary (over forty years on this subject) in a lengthy paper in the *Medical Chronicle* (May and June, 1902), with short notes on 182 cases of aneurysm of the thoracic and abdominal aorta in all its marked forms and in those which the various pathologists did not consider severe enough to warrant being called aneurysmal. Mr. Somerford looked up the records from 1909 to the present date, but for sacular aneurysm only, and has added the 43 cases he found notes of to 168 of this form previously recorded by me.

Without going into details of all the causes of death, it will suffice to say how often it occurred from exhaustion or sudden heart failure and how often from rupture. This the subjoined table shows, and it will be seen that rupture occurred in less than half of the cases.

TABLE V—Heart Failure and Rupture as a Cause of Death

	Number of Cases	Exhaustion and Heart Failure Percentage	Rupture Percentage
Sacular aneurysm			
First part of the arch	64	54.7	42.2
Second and third parts of the arch	63	39.0	33.3
Descending thoracic aorta	23	35.7	53.5
Abdominal aneurysm	15	13.3	80.0
Dissecting aneurysm	6	50.0	50.0
Dilatation	35	57.1	28.5
Total	211	47.2	41.7

I have much pleasure in thanking Mr. Somerford for his valuable help in the preparation of these notes.

TWO FORMS OF DERMATITIS DUE TO THE USE OF METHYLATED SPIRIT EXTERNALLY

BY

P. B. MUMFORD, M.D. M.R.C.P.,

CLINICAL ASSISTANT MANCHESTER AND SALFORD SKIN HOSPITAL,
ASSISTANT TO THE DERMATOLOGIST MANCHESTER ROYAL
INFIRMARY, VISITING PATHOLOGIST PARKSIDE
MENTAL HOSPITAL

THE increasing restrictions imposed by the excise authorities on the use of alcohol have led to the occurrence of various irritations of the skin in persons who are compelled to use medicinal alcohol. Amongst those hitherto unaffected are surgeons who use spirit for the purpose of disinfection and also harddressers employing spirit lotions and spirit soaps. Prosser White notes that pyridine and methyl alcohol used in polishing trades may give rise to chronic dermatitis of the hands.

During the last twelve months an outbreak of severe dermatitis occurred amongst the surgeons at the Manchester Royal Infirmary, and more recently a closely comparable eczema has been produced amongst the employees of a certain firm of barbers in the same town.

The dermatitis occurring in the hospital was produced on the hands and arms of five members of the surgical staff and several theatre nurses. The condition was proved to be due to the alcohol by a process of exclusion of all other factors—the soaps, the disinfectants, and the process of laundering being changed without effect. When the use of spirit ceased, the dermatitis ceased also. The lesions were of a dry eczematous type and affected particularly the webs of the fingers, the wrists and the forearms. The lesions were intensely irritable and commenced within twelve hours of exposure, in certain cases fissuring of the skin and superficial bleeding occurred when the trouble became severe. Only one of the persons affected was predisposed to eczema. The exact chemical irritant concerned in these cases was not isolated, but a change of source of supply checked the appearance of lesions.

The outbreak among the barbers was more extensive and more severe in its results, although two of the cases occurred in men who had had general eczema (from unrecognized causes) elsewhere on the body. Ten definite cases were found within a few months, and in all these the men had been in the same occupation for many years—periods varying from three to twenty years. Several of the other employees complained of itching, burning and tingling of the hands after using certain of the preparations. The ten cases examined showed the following characteristics.

Case 1—Aged 46. Complained of irritation of the hands and wrists for two weeks. Suddenly developed a very severe dermatitis with oedema, fissuring, pain and general desquamation of palms, anterior surface of wrists and between the fingers. The condition settled rapidly on cessation from work and application of sedative lotions. In the employ of the firm four years.

Case 2—Aged 28. Complained of burning of the hands during the last six weeks. Developed blisters on contiguous surfaces of fingers and on palms after using friction lotions. Condition almost disappeared during the forty hours rest provided by the week end. Stated that he has produced a dermatitis of the face by the application of friction lotion to his chin. A dotted vesicular condition of the palms with pruritic erythema was produced by the giving of three seip applications during one day. In the employ of the firm five years.

Case 3—Aged 33. A very severe case with intense oedema and serous exudation of both hands and wrists. This was the first case affected and was the most severe. He now appears to be sensitized to any form of methylated spirit and can only work with rubber gloves when compelled to use spirit shampoos or frictions. Was employed for five years.

Case 4—Aged 35. Irritation commenced in July 1925. He persisted in his work for ten days in spite of mild desquamation. Suddenly the hands became inflamed, oedematous and dehydrated freely. The fingers were so inflamed as to prevent flexion. Pressing and bleeding followed. The wrists also were affected. The condition disappeared entirely within two weeks rest. He resumed work but after giving two applications of lotions the entire dermatitis recurred in an even more severe form. Has been in the employ of the firm for fifteen years.

Case 5—Aged 35. Has had recurrent mild dermatitis of his hands on several occasions. It always disappeared after a week's rest from work. After using the applications he feels a biting sensation all over the hands—if this is repeated the skin peels off and the hand swells up, reddens and becomes very irritable. He states that attacks can be prevented by oiling the hand before employing lotions or frictions, though several applications will penetrate through this and give rise to trouble. At present he has a mild squamous dermatitis which is almost entirely interdigital. This is a patient who has had dermatitis elsewhere on the body previously. Has been in the employ of the firm three years.

Case 6—Aged 35. Has a moderately severe dermatitis on the right wrist and on the webs of the fingers. States that he has a marked burning sensation after the use of any of the spirit lotions.

Case 7—Aged 20. Has some dermatitis of the backs of the hands and wrist with dry scaling and fissuring. This disappears when he is away from work for a few days. Complains of irritation after the use of friction. Has been in the employ of the firm twelve months.

Case 8—A milder case showing dry slightly erythematous fissuring and scaling on the skin on the webs of the fingers of the left hand. There is some slight dermatitis also on the right hand which is very irritable at night. Has been in the employ of the firm for three years.

Case 9—Exactly similar to Case 8. Duration in both cases one month. Has been in the employ of the firm six years.

Case 10—Shows a chronic and scaled patch of dermatitis about three inches in diameter over the first interphalangeal space of the right hand. Has been in the employ of the firm for six years.

The firm concerned gave the writer every assistance in investigating the cause of the outbreak, and a full analysis

of all possible irritants was made, with the following findings

The "dry shampoo" contained approximately 50 per cent water and 48 per cent alcohol. There was a heavy deposit of a gritty nature present which proved to be almost entirely potassium carbonate. Small quantities of colouring matter and scent were present also. It is to be noted that no pyridine was present. The bottles are of necessity shaken before use and it may be concluded that the deposit is evenly shaken throughout the mixture and would therefore be inoculated into the hands were any fissuring present. It is worthy of note that the relative concentration of alcohol and water is such as to precipitate crystals of potassium carbonate. These are palpable in the lotion for a few seconds when rubbed on the hand until the evaporation of alcohol allows them to redissolve in the water. Under the microscope they are seen to be sharp and needle shaped. Experimental inoculation of these crystals into the hand of a non-sensitized person did not give rise to any irritation except such as is to be expected after the application of alcohol to injured skin.

An analysis of the various "frictions" used showed that one of them contained the following irritants: Pyridine, 0.49 per cent of the total mixture, and 25 per cent of the residue after evaporation on the water-bath. Also traces of arsenic and maline colouring matter.

It appears that the use of pyridine is very common in Continental spirit, and it is likely that the cause of the trouble lay in the use of spirit containing this denaturant by the manufacturers. Evaporation of the particular "friction" referred to above left a residue which was largely composed of pyridine and gave rise to irritation of the skin when rubbed in. It is realized also that when the friction is applied to the scalp the evaporation of the alcohol will result in a further concentration of the irritant material.

I am indebted to Dr. Sivatar and Dr. Gibson of the Manchester and Salford Skin Hospital for permission to report on three of the cases which came under their notice and to Mr. H. C. Taylor for the analysis of the materials employed.

COMMON MISTAKES IN THE TEACHING OF PHYSICAL TRAINING

BY

H. B. HILL, M.B., M.R.C.P., SURGEON-COMMANDER, R.N.,
ROYAL NAVAL PHYSICAL AND RECREATIONAL TRAINING SCHOOL,
PORTSMOUTH

Now that forms of exercise and physical training are applied and used in colleges, schools, etc., the following remarks on the breathing exercises might be of interest, especially as medical officers are entering more and more into matters of education and school life.

Breathing Exercises

A clear distinction should be made between a pure breathing exercise and an exercise designed to exercise the muscles of the chest. A pure breathing exercise should, of course, be performed without any movements of the arms or other parts of the body.

In deep breathing the arms should hang loosely by the side, and the muscles of the body be relaxed, in order that the diaphragm may descend to the utmost, and that the capacity of the thorax may be increased to its fullest extent unimpeded by any other muscular movement. The abdominal muscles especially should be relaxed. The severe restriction to breathing which takes place when the arms are moved and the head pulled back can be watched by anyone.

Exercises designed to develop and train the muscles of the chest should be called "chest exercises."

The Straight Spine

It has been taught that the ideal spine is the "straight" spine. This word "straight" has led to considerable confusion in the teaching of gymnastics.

The medically straight spine is the one which gives an erect carriage to the body, has all its natural curves in

correct proportion to one another, and is quite free from any lateral curve. In the other form of straight spine the word has been taken in its literal sense. This faulty spine is illustrated in diagrams and described in words as being as straight as a chimney stack, and free from all its natural curves, the vertebrae are piled up on top of one another like a child's single column of twenty-four bricks, the cervical and coccygeal curves only being shown. This, of course, is not meant by the word "straight."

It is wrong to tamper with or over-correct the normal curves of the spine, the danger being that abnormal curves are produced elsewhere. MacKenzie, writing of the bantam or pointer pigeon type of chest, in which the chest becomes pushed forward and upward, and the lower spine over-extended, forming a marked exaggeration of the natural lumbar curve, says: "This posture is always the result of faulty teaching, and is an exaggeration of the correct standing posture caused by the mistaken efforts of the teacher to over-correct faults" (namely, the "round back" or "goillon" type).

If an abnormal curve is present then the patient should be transferred from physical training or gymnastic instructors to the care of the doctors.

Leg Exercises

Confusion has also arisen as regards leg exercises.

It has been taught that after heavy exercises leg exercises "deflect the blood" from the heart, and so cause the heart and diminish the pulse rate, that leg exercises stretch blood vessels, and so the legs contain more blood and that they have a "calming effect" on the pulse and respiration after heavy exercise. All of this is incorrect.

Writing on leg exercises Pembrey says:

My chief criticism is that there appears to be prevalent a wrong idea of the physiology of respiration and circulation. Thus some exercises are commended because they are thought to stretch the large blood vessels and increase their capacity. It is apparently forgotten that most of the large blood vessels are placed so near the bones that little or no stretching can take place even if stretching were desirable.

A man after cross-country running has had a smiffet of leg exercise and his legs have as much blood in them as they can hold. Another leg exercise imposed on him now can only have one result—the state of rapidity of his pulse and breathing are prolonged, which is a point to be guarded against.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL

DIRECT FRACTURE OF CLAVICLE WITH SYMPTOMS SIMULATING CERVICAL RIB

We recently saw a boy who had been knocked down by a motor car. He had halted on a dark evening by the side of the road on the edge of the sidewalk, and was stooping well down, engaged in trying to light his bicycle lamp, when he was hit by a motor and tossed on the sidewalk. When lifted up he was unconscious, and his bicycle only fit for the scrap heap. He was taken to the surgery of a near-by medical practitioner, who set his broken collar-bone and directed his friends to take him to his home.

He was seen by one of us on the following day, he was still unconscious and the temperature was raised. As the collar-bone seemed to be doing well the adhesive plaster was not removed till the fifth day, it was then impossible to ascertain whether he was hit on the point of the shoulder by the radiator or mudguard or not. An ordinary oblique fracture of the clavicle just external to its middle presented itself. Behind and above the clavicle, in the posterior triangle of the neck, was a blunted swelling. It was slightly movable, painless on pressure, and pointed obliquely upwards and outwards.

On the opposite side of the neck a small blunted swelling was to be felt. We came to the conclusion that it was a case of a cervical rib, springing from the anterior limb of the transverse process of the seventh cervical vertebra on the right side, and that there was a corresponding small attempt at one on the left side.

The general appearance of the boy almost forced one to consider that there was some abnormality. He was

aged 14 years 2 months, and had a peculiar shaped head. The parietal bones met at an angle, like the two sides of the roof of a house. He was mentally deficient, could not be taught to read, but had been able to do general handyman's jobbing work. We were told that the shape of the head and his mental deficiency were the result of severe delivery with instruments owing to little pelvic room.

During the course of attendance we ascertained that there was frequently pain in the neck and a feeling of pins and needles down the arm. As soon, therefore, as it was convenient we had a skingram taken both for diagnosis and with a view to treatment by excision of rib with its periosteum. The x-ray picture showed a frac-

tured clavicle and fractured first rib, but no trace of a cervical rib.

It is obvious that the first rib and clavicle were broken by direct violence from above downwards on the outer end of the clavicle by the impact of the motor car, and the unopposed action of the scapular medius muscle, tilting up the proximal end of the broken rib together with the callus, gave the impression to the examining finger of a cervical rib.

The boy ultimately made a good recovery.

J KENNEDY, M.B., F.R.C.S.I.

CONGENITAL DUODENAL ATRESIA

HAVING read with great interest Dr H C Cameron's most instructive lecture on duodenal atresia in the BRITISH MEDICAL JOURNAL of April 25th (p 765), and noted thereby the extreme rarity of the condition and the scarcity of reported cases in the literature, it occurred to me that the following case would be worthy of publication.

A female infant 3 days old was admitted under my care with a diagnosis of hypertrophic pylorus. This was the last of a family of ten children and was delivered after a perfectly normal labour. It appeared quite healthy at birth and slightly above the average weight it was not premature. The history sent with the infant simply stated that it had been vomiting continuously since birth and that it would not take the breast or any other food, any attempt to feed it was immediately followed by vomiting. When examined the infant appeared rather listless and weak but there was no marked evidence of dehydration or wasting. No abnormalities of development were observed during the very thorough routine examination carried out by the house-surgeon and the ward sister. The vomiting was not of an expulsive type but was generally a copious and frequent regurgitation though the ward sister noticed that the vomit was somewhat forceful and was once projected several inches. The vomit was greenish brown obviously containing a large quantity of bile. It had also a disagreeable almost faecal odour but there was no microscopic blood in it. This vomiting started from the day of birth.

The Stools.—Several meconium stools had been passed without any apparent effort or pain. There had been no opportunity for the stools to change to the yellow milk type as no food had been digested. No rectal examination was made but there was no history of passage of any mucus or blood. There was no excoriation of the skin of the buttocks. The child did not appear to be in any pain and there were no signs of painful colics such as screaming or drawing up the legs.

Jaundice.—The child was markedly jaundiced much more deeply than the slight jaundice of haemolytic origin so often seen in the newborn.

The Abdomen.—There was no obvious distension either general or local. The abdomen was resonant all over but not hyper-resonant. It was soft to palpation no coils of bowel in spastic contraction could be felt and there was no evidence of any free fluid or peritonitis. The stomach outline could not be observed, a most careful inspection failed to show any peristaltic waves either gastric or intestinal nor could any be induced to appear by applying friction or scratching. Frequent attempts to palpate any mass in the pyloric region were equally unsuccessful although at one time I had a vague sense of a movable thickening in the pyloric region (the operation proved that this must have been inaccurate). Unfortunately no x-ray examination was made.

Immediate operation was decided upon as it appeared that the child must surely become weaker the longer it was left since no food was being retained. Immediately prior to the operation an attempt was made to outline the stomach and gain some idea of its size by passing a catheter down the oesophagus and running sterile water into the stomach through the tube. The catheter passed quite freely into the stomach and about 4 ounces of fluid was run in without difficulty whereupon it started to regurgitate gently through the mouth and nose. This quantity did not seem to render the stomach outline any more definite.

Operation.—The stomach appeared normal in size and shape and showed no obvious hypertrophy. It seemed to be capable of holding about 6 ounces. The pylorus was not thickened nor did it feel harder than normal. Commencing about half an inch distal to the pylorus the duodenum suddenly narrowed down to what looked and felt like a solid cord of only about 5 or 6 mm diameter. This extended throughout the second part of the duodenum which was observed to become normal again in its third portion. As it was thought that no canal existed I decided to perform jejunostomy in order to be able to feed the infant by this route for a few weeks with a view to doing a gastro-enterostomy when it should have become stronger. However the child only survived operation by a few hours.

Post mortem. The stomach was found to be perfectly normal the pylorus was normal and not obstructed by any valvular or muscular thickening. About one and a half inches of the duodenum were constricted to the size of a small pocket book pencil. This constricted area occupied the second and part of the third portions of the duodenum. There was however a small lumen traversing the whole length of the constricted area. It was wide enough to admit a packing needle with some difficulty. The walls in this area appeared of normal thickness but the mucosa (if such actually existed) was deeply injected and of reddish brown tint in contrast to the very pale mucosa of the normal part of the duodenum. No microscopic examination was made.

ELEPHANTIASIS OF THE BREAST

THE two photographs reproduced herewith illustrate a case of elephantiasis of the breast before and after removal. Elephantiasis mammaria is, I believe, a not very common tropical disease.

The woman belonged to the Mendi tribe in Sierra Leone. The duration of the growth was about five years, and its weight after removal was 40 lb. Its elephantine structure was demonstrated by a histological examination.

I am indebted to Professor Blacklock and Dr Gordon of the Sir Alfred Lewis Jones Research Laboratory, Freetown, for the photographs and pathological report.

Reviews.

THE WAR HISTORY OF THE NEW ZEALAND MEDICAL SERVICES

IN the preface to the second volume of the official *General History of the Medical Services* during the great war reference is made to the probability that greater detail regarding the work of individual medical units would be forthcoming on the publication of the histories of Territorial and Dominion medical services. This has now to a great extent come true by the publication within the last few months of two volumes on the war history of the Canadian Medical Services, a review of which appeared in the *BRITISH MEDICAL JOURNAL* recently, and of an exhaustive volume on the *New Zealand Medical Services in the Great War*, by Lieut.-Colonel A. D. CANNERY, of the New Zealand Medical Corps. Just as Colonel Snell's Canadian volume provides a study of the work of medical services within a corps area of operations, Colonel Cannery's provides us with an excellent record of the work of medical services within a divisional area on the Western Front, as well as of the wide experiences of the New Zealand field medical units and regimental medical services with a brigade in Egypt and Gallipoli and with a cavalry division in Sinai and Palestine. It thus contains a mass of instructive reading.

In the opening chapters the defective administration and organization of the New Zealand Medical Corps on the outbreak of war and the manner in which the medical services were hampered by the dual and in some respects triple control of different Government departments during it are described. When war was declared the Director of Medical Services had no assistants, the four principal medical officers of districts had no sanitary officers, and the medical units were below establishments. The New Zealand branch of the Q.A.I.M.S. had a ration-master, but no names were on its roll. In a final chapter the subsequent efficiency and expansion of the service are traced in interesting and accurate detail.

The New Zealand Medical Corps had the earliest experience of the war in the bloodless occupation of Sinai on August 29th, 1914, but, although there was no fighting, the medical officers found themselves left in the lurch by the German medical staff, who refused to remain in charge of the civilian patients in the civil hospital in Apra and carry on the important ophthalmic work of the island. The whole staff had consequently to be deported. When a brigade was sent to Egypt in 1914 its field ambulance was hampered on disembarkation by its horses and ordnance equipment having been sent on a different transport from that conveying the personnel and wagons. How often this lesson has been ignored in the history of the embarkation of medical units with an expeditionary force! An account of the preliminary difficulties in Egypt is followed by four chapters of vivid description of the experiences and work of the New Zealand medical units on the Gallipoli peninsula. They reveal in more detail than does the British official medical history the horrors and deplorable sanitary conditions of the ill-fated but gallant force that landed there in 1915. By January 1st, 1916, New Zealand had sent 27,902 officers and men overseas. Of these, 2,638 were dead, missing, or prisoners of war, 4,857 were wounded or sick in hospital, and 3,111 had been repatriated.

A New Zealand Division was mobilized in Egypt of the 17,200 who remained there after the evacuation of the peninsula. It joined the Second Australian Corps, and went to France in April, 1916. Twelve chapters, forming the chief section of the volume, record the history of its medical services during the battles in which it was engaged on the Western Front. The working of regimental and posts and regimental medical services is especially well told and supplies a mass of information such as is lacking in the British official medical history. The narrative of the capture of Flers on September 14th, 1916, is typical

of this. It is taken from the diary of Major Noel Johns, whose brief descriptions of the Somme and other battles are frequently quoted, and who fell himself on the field of battle in August, 1918, near the spot where he describes the events in which two other gallant officers of the New Zealand Medical Corps, Captain Gilbert Bogle and Major A. Martin, lost their lives in September, 1916. The attractive personality of these three fine young officers can be seen at a glance from the photographs of them which appear in the volume.

The chapters on the Western Front are followed by a chapter on the experiences of the New Zealand Mounted Brigade Field Ambulance with the Australian Mounted Division in Sinai and Palestine and during the raids on Amman over the Morb plateau in 1918, when sick and wounded had to be brought back to a distant base over difficult country by hand carriage and pack transport, but arrived at the base hospital in wonderfully good condition. In similar operations in future ambulance aircraft and ambulance aeroplane squadrons will no doubt surmount the medical difficulties of operations such as these, just as they are now doing in Syria, Morocco, and Iraq.

The concluding chapters deal with demobilization and reconstruction, and also record the outbreaks of influenza and pululent bronchitis from which the New Zealand troops suffered severely at the close of the war. There are several useful statistical appendices, 124,211, or over 50 per cent of the male population in New Zealand between 19 and 45 years of age, were mobilized, and 100,444, or over 40 per cent, embarked for overseas, 753 officers and 15,549 other ranks lost their lives, and 1,720 officers and 39,542 other ranks were wounded. In an analysis of the causes of death from disease among 92,860 of the troops influenza is shown as accounting for 152 deaths, typhoid fever for 126, meningitis for 115, and pneumonia, including bronchopneumonia and septic bronchitis, for as many as 578. Out of 358 officers and 3,248 other ranks of the New Zealand Medical Corps who went overseas, 12 officers and 123 other ranks were killed or died of wounds, 7 officers and 49 other ranks died of disease, and 35 officers and 426 other ranks were wounded. Of 550 nursing sisters, 13 died, 10 from drowning by enemy action. Other appendices contain a note on medical arrangements for the landing at Anzac and for the dysentery which occurred, the scale of rations there, an account of the New Zealand divisional medical school of instruction in France, and nominal rolls of officers and men of the New Zealand Medical Corps who died or were wounded, and of those who received honours and awards. There is a good index, but only three maps, in a pocket of the cover, on none of which are the positions of medical units indicated. The reader will consequently find it impossible to follow the narrative without referring to the numerous sketch maps in the volumes of the New Zealand official history, which have been published under the title of *The War Effort of New Zealand*. Another defect is the number of misspellings and date errors that are somewhat too prominent. They are obviously due to insufficient proof-reading. Otherwise this volume of the war history of the New Zealand medical services is beyond all praise, and, as stated by Sir William Macpherson in a short and appreciative introduction, will be welcomed alongside the volumes of the British official medical history as an essential portion of the medical history of the war as a whole.

THE STOMACH AND UPPER ALIMENTARY CANAL

Dr. T. IZON BENNETT is well known for his work on Reflux's fractional test meals and on other aspects of gastric physiology and pathology at Guy's and the Middlesex Hospitals, and his recent monograph on *The Stomach and Upper Alimentary Canal in Health and Disease*, which is refreshing for its originality, is thoroughly worthy of his past record. It begins with the physiology and pathology of the month and ends with a consideration of the duodenum,

Dr Henry H. Dixon
 1924
 D Sc FR S
 813 20 80
 London

Dr. Dixon's lectures on the rhythmic movement of plants, and his theories of cohesion and tension, are of great importance to the study of plant physiology. The view which Dr. Dixon holds, in opposition to vitalistic theories, is that the structural characteristics of the wood of trees are such that water naturally or completely filling it inevitably passes into a state of tension, when it is reduced in volume by abstraction from one or both ends. He believes that in normal circumstances, abstraction of water is effected by the cells of the leaves in contact with the upper ends of the ramifications of the wood and so the water coming from the lower parts of the plant is drawn up in a state of tension living from these upper terminations. In the first of his three lectures Dr. Dixon reviews the experimental work carried out since 1914 by himself and other botanists, and finds that the position of the cohesion theory has been materially strengthened thereby. The second lecture, on the function of the living elements in lifting the water current deals chiefly with the views of Bose on the rhythmic activity of plant cells and reports a number of experiments by Dr. Dixon and others which contradict Bose's hypothesis. In the third lecture Dr. Dixon discusses the part played by the transpiration current in the transport of substances throughout the plant, and brings forward evidence to prove that the cohesion theory, in addition to solving the old problem of the ascent of sap, offers a

due to the mechanism of the transport and distribution of organic substances in plants. Though these lectures are intended primarily for botanists they deal with a subject in which every type of biologist has an interest, and we think that some of our readers will be glad to know where to find a recent account of this debated question.

A GERMAN CYCLOPAEDIA OF OTO-RHINO-LARYNGOLOGY

A vast system of otology and laryngology in nine volumes, under the general editorship of DR. KRAUSE and KÄHNEN, has been planned to replace handbooks of otology and laryngology by SCHWARTZ and HERMANN respectively. The first of these immense volumes contains 1,068 pages and 709 illustrations, and it appears to be conceived on a similar scale. It is responsible for otology and laryngology and the other subjects now included under that term. There are one hundred and twenty-two contributors to this colossal undertaking.

The first volume contains a complete account of the anatomy and physiology of the nose, pharynx, and larynx, in which no detail of embryology and histology is lacking. In this part there is also a description of the nervous connections of these regions, which include the trachea and bronchial tubes. The rest of this volume is devoted to the general pathology and methods of examination of the nose and nasopharynx down to the bronchial tubes. Vast as it is, this volume forms only an introduction to the study of rhinology and laryngology. Its size alone must excite a feeling of awe, but this is enhanced by the wealth of material, the precision and clarity of the hundreds of illustrations, many showing histological details in exquisite colour, the exhaustive bibliography, and finally the reputation of those whose names form the list of contributors.

To attempt a detailed criticism of such a work would be futile, beyond recording the general fact that work and methods of examination elaborated in America and Great Britain during recent years are to a great extent ignored. The German mentality seems unable to discard this chauvinism but in a literary undertaking so comprehensive in character it constitutes a serious deficiency. There is presented, however, an encyclopaedia of German laryngology, the product of many ardent workers directed by two masters, and as such it must compel respect in spite of the defect we have pointed out.

REFRACTION OF THE EYE

Among the conditions that affect the eyes and cause discomfort none is more common than some error of refraction or accommodation or muscle balance. Errors of refraction cannot be treated as things apart; they are more or less troublesome according to the general habit and work of the patient. It is therefore necessary that every book upon the anomalies and diseases of the eye should treat of errors of refraction. But for all that there is a very real place for separate books upon the anomalies of refraction and amongst these Mr. INVER CLARKE'S *The Errors of Accommodation and Refraction of the Eye and their Treatment* has won a high place in the regard of students and practitioners. It has now reached a fifth edition. The first edition issued twenty years ago, was founded on lectures delivered to graduates. Now it has become a well established and balanced handbook. The author carries the student through a course of instruction each part of which is related to practical work. Beginning with elementary optics he proceeds to the optical properties of the human eye and so to the divergences from the common standard. His insistence upon the influence of the general health upon the working of the eyes is right. He says:

There is a wide difference in the accommodative power of different individuals when the accommodative power is lower than

normal it will be found that the individual is older, and looks older, than his age and vice versa. Premature presbyopia which is really premature senility, is provoked by various conditions, but intestinal crisis is perhaps the commonest cause. A small error of refraction uncorrected not only tends to lower the power of the ciliary muscle by the constant drain on its energy, but tends to hasten the sclerosing processes in the lens.

The author still adheres to the original practice of describing retinoscopy as the "shadow test," and in the terms of shadow. There is long precedent behind this, but there is advantage to the student in describing it as the "light test," and referring the observations to the movements of the light reflex. Experience shows that by the latter method the student gains a more rapid and certain appreciation of what is before him, and that in the end greater accuracy of observation is obtained. But apart from such a criticism as this on a matter of opinion, we have nothing but commendation for the book as a valuable and safe guide to the student and practitioner.

HOMOEOPATHY BY A HOMOEOPATHIST

In his booklet, *Homoeopathy Reasoned Out*, homoeopathy, says Dr. NORTBY, is based upon a great law, and the great law is that "if you wish to cure a disease you must select the remedy which, when given to a healthy man, will produce a similar disease." The great watchword and slogan of homoeopathy, invented by Hahnemann himself, is *Similia similibus curentur*, which means, and can only mean, "Let likes be treated by likes."

Dr. Northby then proceeds to protect himself against the possibility of the law behaving as a boomerang by writing "When I talk of similarity I do not mean absolute similarity—but a general similarity." Furthermore, homoeopathy is not the administration of very minute or infinitesimal doses. "We may deduce a small dose from the law, or we may find by practical experiment that small and perhaps progressively diminishing doses are giving better results than crude or material doses." This has nothing to do with the "main difference between the systems of allopathy and homoeopathy." What sect is meant by the term "allopathy" is not explained but it appears to consist of "old school practitioners," followers, disciples, of Aesclepius, Hippocrates, Huxley, or Sidenham. We are told that mercury is a homoeopathic cure for dysentery, because if given to a man in health it will cause symptoms resembling dysentery. Note how the difficulty with the amoeba and the bacillus is got over by the explanation of "general similarity." So, too, camphor cures cholera because camphor can produce symptoms similar to cholera. Arsenic cures syphilis because one of the most marked features of arsenical poisoning is a chronic skin eruption while "the most perfect simile for the majority of cases of erysipelas and scarlatina is belladonna." One of the few specifics of the "old school" is quinine. Why is it specific for malaria? Nobody ever knew that until Hahnemann himself took 4-drachm doses of cinchona bark, and was astonished to find that he reproduced in himself an accurate picture of the symptoms of malaria. Dr. Northby gives surgery a little pat on the back. Apparently surgeons are not allopaths and even Hahnemann declared that foreign bodies must be removed by surgery. Consequently tonsils should be removed if they do not diminish in size under treatment. We are left in doubt as to what the remedies are that "homoeopathically chosen may at times have a remarkable effect on cancer." Dr. Northby makes much use of vaccine therapy as evidence for homoeopathy, and states that Sir Almroth Wright, the high priest of St. Mary's laboratory, has admitted that vaccines are homoeopathic. Other witnesses Dr. Northby mentions to the truth of the gospel are Sir Frederick Brunton and Oliver Wendell Holmes, though the latter luckily described homoeopathy as a "myth." Finally, there is the discovery that more than a hundred years ago Hahnemann was reducing inert insoluble substances to the colloidal state, thereby anticipating the activities of some modern drug firms. Well may Dr. Northby close his volume with the slogan, "Dip it up, dip it up—it is all around you, the flowing tide of homoeopathy."

NOTES ON BOOKS

A PAMPHLET dealing with the height and weight of school children⁸ has been issued by the Director of the Children's Clinic in the Berlin University, in conjunction with the German Ministry of Health, it contains data intended to form a basis for the systematic inspection of school children in reference to their development and nutritional condition. The publication relates solely to the question of weight and height, and an endeavour has been made, by deductions from extensive statistics carefully prepared, to obtain figures representing the normal condition of children in these particulars at different ages. It is pointed out that if the scheme is to have any practical success it is necessary that school medical officers should undertake regular anthropometric investigations, and, more particularly, that the methods employed should be uniform and the scientific uses of statistics thoroughly understood, in order that results may be comparable. The methods of measurement that have proved to be the most satisfactory are described, and the results, collected from twenty-one towns and two country districts, involving measurements of nearly a quarter of a million individuals, are embodied in tabular and graphic form. The figures are grouped in age classes, and these are subdivided in reference to the normal, subnormal, and supra-normal heights and weights. The normal half-yearly increase in weight and height is also given. The course of development varies between males and females in Germany, as in this country. At the age of 6, boys are taller and heavier than girls and the difference is somewhat accentuated up to the age of 10, at this stage girls increase in height and weight more quickly than boys and overstep them in these respects at the age of 11. The difference increases up to the age of 14, when a marked development occurs in boys, while that of girls slows down. An extensive bibliography is appended.

Dr ELIZABETH SLOAN GRESSER has edited a volume entitled *Health and Psychology of the Child*⁹ which is intended to help those who are responsible for the care and upbringing of the young. The editor believes that environment during the early days of life makes an indelible impression on the whole development of the individual, and she believes that a better understanding of psychology and the needs of a child will do much to prevent disorders grouped under the term 'psychoneurosis'. That factors other than those dependent upon early training are responsible for the production of abnormal personalities the author realizes when she asserts that the medical profession must devise a humane method of preventing the propagation of the mentally unfit. She thinks, perhaps a little optimistically, that such a measure, combined with improved environment for the children of all classes, would uplift the physical, mental, and moral stamina of the race in two generations. The volume contains thirteen chapters by different contributors, and has a foreword by Sir Maurice Craig. Both the physical and mental aspects of child life are considered, and all the writers express their views simply and clearly. We have no doubt that the book will be found helpful by parents and teachers, and it may be recommended to all those interested in the welfare of children.

SIR RABINDRANATH TAGORE has a wide reputation and his works have a considerable vogue in certain circles. His latest book is a drama in one act, entitled *Red Oleanders*¹⁰. The theme is symptomatic of the attitude of many Indian writers, particularly of such of them as lead sheltered lives. It is a fierce protest against organized life and a pathetic yearning after a life of nature love. The scene is laid in a mining town. Diggers forgather, talk, and grumble, governors manoeuvre and order, the preacher soothes with words, the king is veiled in mystery, and a woman, a spirit of Nature, in Rudra Pan, stirs up the hunger of the populace for its lost simplicity. The story ends in riot and death which is reckoned to be the recovery of liberty. We should judge that as a play it would not be acceptable by the most eclectic of repertoire theatres: the dialogue is fragmentary, but there are a few felicities of the sort that has made Tagore's reputation—for instance, 'Underground there are blocks of stone, iron, gold,—there you have the image of strength. On the surface grows the grass, the flower blossoms,—there you have the play of magic. There must be beauty even in hell, but nobody there can understand it that's then cruellest punishment'.

In *Uncle Archie His Nights with a Nephew*¹¹ Dr WILLIAM CULLEN is reminiscent in an interesting and humorous vein about men and their doings, especially Glasgow and its Medical School in the past. There are many good stories, particularly some about the late Sir William MacEwen, and the history and origin of Sydney Smith's historical note about the need of a surgical operation to get humour into a Scot. Written in an easy, happy mood, the text is varied with many appropriate verses.

MEDICAL AND SURGICAL APPLIANCES

An Ultra violet Ray Outfit

Dr F. C. EVE, F.R.C.P. (senior physician, Royal Infirmary and Children's Hospital, Hull), writes. At present the available sources of ultra violet rays are (1) the mercury vapour lamp, which has a short life, produces no heat rays, and can easily be overexposed, (2) the tungsten arc, rich in short rays but poor in heat rays, and costly in carbons, (3) big arc lamps, such as the Eidenow, with a very long arc, which jumps in a draught, they are wasteful of current, I am told.

The novelty in the system, which has been working satisfactorily at the Hull Royal Infirmary during the last five months, consists in forcing the electric pressure designed for four street arc lamps through three lamps to eliminate the consequent overheating then coils have to be rewound by an arc lamp specialist (for instance, Mr. Pardoe of Hull). Then

one gets three big arcs which do not jump, and which only waste 10 per cent of the current in resistances instead of the usual 50 per cent. The three lamps are suspended in a row 15 inches apart (adjustable), at a height alterable by a winch (seen on right).

The other advantages are

- 1 The four patients are recumbent and hence very comfortably resting equidistant from the arcs.
- 2 The whole skin from head to foot is evenly radiated—ten minutes front and then ten minutes back initially.
- 3 As the energy is emitted from three sources instead of one the skin can be exposed at 2 feet instead of the usual 3 feet. This increases the radiation effect as three squared is to two squared—more than double.
- 4 Street arc lamps are now largely superseded and hence can be bought very cheaply.
- 5 Ordinary carbons are used the total cost of running is estimated at 1s. an hour.
- 6 The total radiation imitates hot sunshine so that the sensation of basking is very enjoyable. Tested by a standard methylene blue tube on the patient's skin, one unit of fading is produced in twenty minutes at our usual working pressure. This is equal to several hours sunshine: erythema and pigmentation are produced.
- 7 The two (novel) double decker couches enable four patients to be treated at once, they are fitted with yacht's wire mattresses.

The outfit is in a small room (14 ft. by 12 ft.) next the medical wards, and is used as an ancillary to general medical treatment. Certainly the patients like it and say they feel much benefit. My general impression of the clinical effects is favourable. I am in no way an retino-therapeutic expert, but if it is true that our patients are suffering from a deficiency of sunshine it is clearly the business of a general physician to attempt to supply that deficiency by artificial means.

A Blood Transfusion Apparatus

Dr DANIEL McLELLAN (Vancouver, B.C.) sends an account of an apparatus for the direct transfusion of blood, with the introduction of citrated saline solution into the blood stream as it passes through the apparatus. An all glass 20 ccm syringe is attached by means of an adapter and rubber tubing to the stem of a Y shaped glass tube. The intake arm of the Y tube is connected with the needle for the donor, while the exit arm is connected with the needle for the recipient. A cone shaped glass valve is placed on each side of the Y tube the one on the donor side has its apex pointing towards the donor the base of the one on the recipient side facing the recipient. Between the donor needle and glass valve next the donor a second Y shaped glass tube is placed to the stem of which a rubber tube 20 inches long is attached, connecting with a 300 ccm burette for citrate and saline solution. On this tube is a Murphy screw clamp and a cut off clamp. Needles are 15, 14, or 12 gauge. The tubes should be placed in the form of an L or L reversed or a T, the recipient's table forming the foot of the L or the cross of a T, the donor's arm slightly outward the recipient's arm at right angles to his own body. The donor's needle is inserted towards the finger tips the recipient's needle towards the heart. A standard with an adjustable goose neck attachment stands in the angle formed by the two tables from this goose neck the burette is hung. A mixture of 2 ounces of a 3 per cent solution sodium citrate with 18 ounces normal saline is used as diluent. Where small quantities of blood such as 6 to 10 ounces are being transfused the citrate may be cut off entirely after the first stroke of the syringe has been made. To expel air from the apparatus the long tube is clamped off the burette is filled with warm citrated saline solution, and the Murphy clamp is screwed down to allow a moderate flow. The needles are immersed in a bowl of citrate saline solution the cut off is released, and a few strokes of the syringe will expel the air the last bubble may be removed by inverting the syringe. The automatic action of the valves now becomes evident as the intake valve opens the exit valve closes and vice versa. To regulate the flow of the citrate-saline solution place a suitable clamp on the rubber tube between the (burette) Y tube and the release the cut off clamp unscrew the Murphy clamp tight, the solution comes from the donor needle drop by drop about 100 to the minute. The pinch cock is taken off and placed on the tube between the (burette) Y tube and the donor needle. The recipient needle should be inserted first immediately loosening the turncock and releasing the cut off clamp. The liquid begins to flow slowly through the apparatus into the recipient giving no chance for the formation of clot and thus bidding over the interval of time between the insertion of the recipient and donor needles. The donor needle is then inserted the pinch-cock removed and by steady easy strokes the blood is pumped from the donor to the recipient the strokes being counted. By deducting the quantity of citrate saline solution from the total the actual amount of blood transfused is estimated. The apparatus may be obtained from Messrs Down Bros Ltd 21 St Thomas's Street S E 1

valve opens the exit valve closes and vice versa. A Modified de Ribes's Bag

Dr J E HEPPER (Frimley, Surrey) writes to bring to notice a modification of de Ribes's bag which he has devised. The

object of the bag he says is to play the part of the membranes in those cases where the membranes rupture early in labour. The bag when folded can be introduced into the uterus when the cervix is the size of a shilling by means of long ovum forceps. It is pear-shaped 2 1/2 inches in diameter at the broad end and 4 in long and is made of rubber of medium thickness. The thin end of the bag is attached to a rubber tube the other end of

which is fitted with a tap. It is important that all air should be expelled before introduction, and that a partial vacuum should be ensured by turning off the stopcock. When the bag has been introduced in the manner described a Higginson's syringe should be fitted to the tap and the bag partially filled with water. One injection is sufficient. It is better to dilute with water than with air. The bag remains in position until the cervix is fully dilated the number of hours in labour being thus considerably reduced. By a special device the broad end of the bag when filled, is concave so that it does not displace the foetal head. The pressure also is evenly distributed outwards against the inner side of the cervix thus producing more speedy dilatation. The bag can be obtained from Messrs Allen and Hanbury's Ltd 48, Wigmore Street W.

MOTOR CARS FOR MEDICAL MEN.

NEXT WEEK'S OLYMPIA SHOW

A FORECAST

By H. MASSAC BUIST

THE nineteenth annual International Motor Car Show, organized at Olympia, Kensington, by the Society of Motor Manufacturers and Traders, under the patronage of the King, will be opened to the public on Friday next, October 9th, and will close on the evening of Saturday, October 17th.

This year's Motor Show will not be so remarkable for the number of entirely new chassis types that will be introduced as it will be for the quite exceptional all-round progress made in twelve months in the matter of developing in detail vehicles already on the market. In the latter connection enterprise takes two forms: the pioneers of designs that are commercial have been always notable for the simple means by which they achieve results. An inspection of engine and chassis improvements made by the rank and file of manufacturers will reveal that at last the majority of them have become educated to the value of clean lines and to the necessity of "tidying up" their engines and chassis to reduce cost, to minimize possible loss of adjustment, and to ensure accessibility whenever that process should become inevitable.

THE QUEST OF ACCELERATION

Of course, these characteristics are apparent also in the majority of the new car types that will be forthcoming. The inspiration of the design of most of these is a clear recognition of the fact that it has been possible for many years to travel as fast on a car, once it has got going, as is desirable but that we are still far from the stage of vehicle evolution which will enable a driver to attain promptly, either from a standing start or after slowing down for traffic or at cross-roads, the speed at which he wishes to travel. That quality we call acceleration. As far as new four-cylinder engined cars are concerned, progress is being attained by the use of lighter reciprocating parts, including aluminium pistons, by developing, or altering the valve system, by increasing thermal efficiency, using higher compression, higher crankshaft speeds, by economizing heat losses, and so forth.

To give an instance, a very successful car in the service of medical men, the Hillman, will appear in entirely fresh guise with a 2-litre side-valve four cylinder engine of such improved performance that this is now a mile a minute machine with proportionately good hill climbing performance, quiet gears that can be changed instantly, as in racing practice, so that neither car momentum nor engine revolutions are reduced in the act, Hotchkiss type front wheel brakes on a much wider and longer chassis, and coachwork developed accordingly. Inspection resulted in my being able to count twenty-two fresh points in the whole scheme, not the least valuable of which is the mounting of the power unit on new-style oil proof fabric insulators.

PURPOSE OF THE SIX-CYLINDER ENGINE

But 1926 will not be known for the development of the four-cylinder engined type, nor for the increasing use of the overhead valve system, recruits to which include Atwood-Johnston and Galloway among those who exploit four cylinder practice. That will introduce the long expected nominal 7-h.p. four-wheel braked small car with light-hand controls, even as Humber will bring forward a 9/20 h.p.

new style light car with a four cylinder engine having overhead inlet and side-by-side exhaust valves. Lagonda introduces a chain-driven, double overhead camshaft-driven, overhead valve, four cylinder 2-litre engined, front wheel braked car, thereby entering a new market, and Straker-Squire re-enters the arena with a new push-rod operated, overhead valve, 1460 ccm four cylinder 11/28-hp engined chassis with Alford and Alder type four wheel brakes, having, however, the Whitehead system of hydraulic operation. About the only other notable firms which will present new moderate sized four-cylinder engined cars exploit the side-valve setting—namely, Swift, with a 1,954 ccm 12/35-hp type with front wheel brakes, Triumph, with a 15/50-hp side-valve four cylinder engined machine, also with front wheel brakes, Clno, with a 1,496 ccm side-valve four cylinder 13 hp engined chassis, with a specially designed spiral bevel rear axle having proportionately very large diameter bearings, and a four wheel brake system absorbing the greater proportion of the speed by chocking the front wheels, and De Dion Bouton, with a £10 tax side-by-side valve four-cylinder 10/20-hp engined, four speed, four wheel braked Rudge-Whitworth wire wheeled chassis at £255 only, with coachwork prices in proportion.

To discover the unmistakable trend of the motoring times, however, we must look to the new six-cylinder engined machines. These are remarkable for their number, for the variety of the systems of their design, and for their quality. The plain fact is that what the four-cylinder engine was to the two cylinder engine type before the war, the six-cylinder engine is to the four cylinder engine to day. By means of secondary force vibration dampers, by using lighter reciprocating parts, and so on, it is possible to give a four-cylinder engine of the highest quality and of expensive production many of the characteristics of a first-class six-cylinder type, but, cylinder volume for cylinder volume, one cannot give it equal acceleration.

More Flexible Performances in all Categories

That is the reason for the introduction at the forthcoming Motor Show of such an extraordinary variety of six-cylinder engined new car types, ranging from the 6-litre overhead valve "Big" Bentley (wherein an overhead camshaft is driven in a wholly novel and unprecedented smooth fashion by triple connecting-rods) the 3,929 ccm double cast-iron sleeve valve six-cylinder engined Willys-Knight, the 3,880 ccm Burt McCullum type single oscillating cast-iron sleeve valve engined 25/70 hp Vauxhall with pear shaped combustion head, the 3,180 ccm push-rod and rocker operated overhead valve 20/60-hp Star, the 2½ litre 18/50 hp overhead valve six-cylinder engined Crossley, the 2,540 ccm overhead valve six cylinder 17/75 hp Daimler, the six cylinder Calthorpe, the inclined side valve 2,565 ccm six-cylinder Calcott, and the 1,776 ccm overhead valve six-cylinder engined Singer down to the 1,500 ccm overhead valve six-cylinder engined Alfa-Romeo from Italy and 1,500 ccm overhead valve six-cylinder engined Steyr from Austria. Other machines could be named, but the foregoing will suffice to indicate the beginning of a tendency to offer six cylinder engined cars of all sizes and prices with power units employing quite strikingly contrasted valve gear practice.

Again among those who have spearheaded in the production of six cylinder engined cars, notable advances have been made this year. There will be on view the first display at any exhibition of the complete range of Daimler cars—including one of only £16 tax rating which is nevertheless capable of travelling at a mile a minute—with the new style light, durable, steel double-sleeve silent valves and a buffer plate system which eliminates the smoke nuisance. Also there will be introduced the "New Phantom" 40/50 hp Rolls Royce with its six cylinder overhead valve engine in succession to the side valve engined "Silver Ghost" type. Armstrong-Siddeley brings forward an overhead valve six-cylinder monobloc 18 hp engined chassis. Only one objection is common to this wealth of enterprise—that smoother functioning which spells greater acceleration and hill-climbing power in conjunction with enhanced flexibility and therefore greater range of performance on the direct line. That, and the provision of greater body accommodation is why Sunbeam will introduce a 30/90 hp

eight-cylinder-in-line overhead valve engined chassis with a notably large diameter stiff crankshaft.

CHASSIS DEVELOPMENT

The most obvious chassis development this year is the increasingly wide standardization of brakes to all four wheels. All Armstrong-Siddeley cars, all Swift, both Rolls-Royce, both Morris, both Rover, both Clno, the new Hillman, and the latest Humber are among the recruits to the practice.

One has already seen several new-style cars, too, wherein the engine and gearbox are insulated from the chassis frame (or subframe, as the case may be) by setting the arms on flexible vibration and noise-absorbing mountings that are oil-proof. Quite a number of Coventry builders are exploiting this system, to the merits of which attention was drawn in these columns last year, though it that time the motor industry was unaware that such a facility was about to become available to it. Another very important forecast made then takes material form now in the new Vauxhall chassis, wherein neither shackles nor pins are used in connexion with the suspension scheme by half-elliptic springs, which need no lubrication, yet do not wear and do not squeak. Nor are the expensive constructions as far as these details are concerned. Further developments along these desirable lines are therefore assured in the evolution of the motor vehicle, for the majority of firms are always afraid to embark on any common-sense fresh practice until they find an automobile engineering house of world-wide reputation holding to lead the way.

PRICES AND IMPROVEMENTS

The rise in the price of rubber, leading to an increase in the price of tyres that was not expected by car builders in the course of the past season, has had an unfortunate effect in retarding the progress of the world wide movement to provide better yet cheaper cars. Manufacturers did not increase prices many of them are compelled to lower them, all are trying to do so. Therefore the only course the majority can take is to provide fewer improvements, or accessories than they intended had the cost of tyres not been raised. Surviving the matter all round, they have done admirably well, for many manufacturers of the highest repute are marketing their cars, not much at appreciably lower prices but in every case in better form as regards one or more details. Clno and Morris are examples of sensational decreases in price, accompanied in each case by quite a number of improvements in detail, all of a practical sort, such as the standardizing of front wheel brakes, and so forth.

Nevertheless, concerning the motor car industry in the broadest sense undoubtedly but for the increase of tyre prices we should have found all cars standardized with mechanically operated wind-screen wipers for the driver and in some cases for the occupant of the seat beside him too. In like fashion, had it not been for the bad effects of the rise in rubber prices—a matter of prime consideration for the medical man—the provision of means for preventing head-lamp dazzle without minimizing the amount of light available to him would have been the general as distinct from exceptional, practice illustrated at next week's exhibition.

PREVENTING HEAD-LAMP DIZZLE

The use of dimmers is a compromise, not a solution of the problem of dazzle, therefore the American industry compromises, and the British industry also. But on the Morris Oxford models there is no compromise, instead, Barker rotating dipping head-lamps of the type used by the King and the Royal family on their Daimler Rolls-Royce and other cars are standardized. There is therefore no longer any manner of doubt that twelve months hence car builders in general will standardize means to prevent head lamp dazzle without in any way limiting the volume or light. There is more than one means of attaining this end and where the builder of the greatest number of cars in the country leads others must follow in due course.

CHIEFLY CONCERNING COACHWORK

The fact that completely successful results have not so far attended the very numerous and prolonged experiments

of car builders in this country is the reason why we shall have to wait yet another year for the advent of the standardized oil, grease, tar, rim, damp, and heat proof frequent body finishes, such as Studebaker has been so exceptionally successful in pioneering in America in big car practice. But Mr Edge has been bestirring himself, and considers that he is justified in introducing a scratch-proof body finish scheme on the A C car.

As regards design, in the middle size categories one British manufacturer after another who has standardized central change speed and gear lever positions is providing offside controls. The salesman's argument that this cannot be done without it being exceedingly inconvenient for the driver to have access to his seat from his own side of the car is absolutely without foundation. Numerous designers have shown for at least a decade how this can be done quite effectively, and if individual designers are so unintelligent as not to avail themselves of common knowledge, at least they cannot pretend that a driver has to enter and leave his seat as often as he has to change speed or use the handbrake. Those seats are inconvenient, to say the least, in cars of restricted accommodation occupied by motorists in winter attire. That is one reason why, even in the small car category, several machines will be presented at the forthcoming show with right-hand instead of central controls. In the case of the most luxurious cars we find Rolls-Royce abandoning a three speed centrally controlled gearbox on the 20-h p chassis, and providing a more compact four-speed still quieter gearbox with offside control.

Other novelties to be shown at the exhibition will be reviewed in these columns next week.

PUBLIC HEALTH SERVICES IN HUNGARY

THE Health Section of the Secretariat of the League of Nations has published a memorandum on the public health services in Hungary, by Dr Alexander De Dobovits, Councillor of Section in the Royal Hungarian Central Statistical Office. Though the population of Hungary is now only seven to eight millions the account of its health administration is longer and more elaborate than that relating to Germany, noticed in our issue of July 4th, 1925 (p 20). The subjects dealt with are grouped under seven heads—public health organization, duties of health personnel, public health institutions for the sick, the campaign against epidemics, temperance campaign, child welfare, and measures for the protection and improvement of public health.

The administrative organization of Hungary consists of a Ministry and three sets of local authorities. The supreme direction is in the hands, not of a Minister of Health so called, but of a Minister of Labour and Social Welfare, who has charge of no fewer than fourteen departments, including sickness, workers' and disability insurance, war victims' relief, poor relief, housing, and child welfare. Each of the departments has a chief and a clerical staff, whilst the Minister has two under secretaries, altogether the staff numbers 336 persons, including the Minister and secretaries, twenty-two medical officers, and four pharmacists. There is a National Public Health Council, which is an advisory committee with medical members. The advisory and administrative bodies of county or urban municipalities are (a) a municipal committee, and (b) an administrative committee. The former has a membership ranging from 48 to 600 according to population; this larger figure must seem extraordinary to readers acquainted with local government in this country. The chief municipal medical officer is a permanent official whose duties include expert medical investigation in police matters and attendance at medico-legal *post-mortem* examinations. He signs and registers the diplomas of medical practitioners and midwives in his area. A district medical officer has more or less similar duties and is a regular permanent county official appointed by the prefect. The capital city, Budapest, has a special organization. The smallest units of administration in Hungary are called communes and possess, within limits, important autonomous rights. Each local authority for an area with 5,000 inhabitants and upwards must appoint a

medical officer of health, smaller communes may be grouped into cantons for that purpose. The officers may practise privately outside their own areas. Medical officers are *ex officio* members of the magistracy and council, they are appointed for life, and among their numerous official duties are medico-legal inquiries.

In general medical practice there has been no reciprocity between Austria and Hungary since 1898. In Hungary a diploma to practise is not conferred until after a year's probation in a hospital. Some foreign diplomas cannot be validated in Hungary. The Minister of Labour and Social Welfare may hold special examinations and grant certificates essential for holding municipal, police, and forensic appointments. Post-graduate tuition at the universities is organized by a central board.

Midwifery practice by women has, since 1921, been confined to those with a legal diploma, previously a certificate by the chief municipal medical officer sufficed as a substitute for a diploma, the course of training covers ten months. Midwifery certificates issued abroad must be validated in Hungary before being effective. Places with 2,000 to 5,000 inhabitants must have two qualified midwives, those with from 5,000 to 10,000 must have three, and above 10,000 an additional midwife is required for every 5,000 of population.

Death certification is compulsory, burial is not permissible without it. Certificates may be given by (a) medical practitioners, (b) persons who have passed a test of competence, or have been trained by a medical practitioner, and (c) in the absence of a certifying official, by a member of the local authority appointed for the purpose. There is a prescribed terminology for specifying causes of death. Burial should take place between forty-eight and sixty hours after death. Where an autopsy is necessary "the police shall conduct" it, but there is no statement as to whether the return examination may be done by a layman.

Pharmacies rank as public health institutions, not commercial establishments, and are under Government licensing and supervision; there is a university diploma of doctor or master of pharmacy, the requirements seem stringent. The price of drugs is fixed by the Minister in an annual tariff, and a pharmacist failing to adhere to it may be punished.

Official medical salaries are graded, they are given in the memorandum in gold crowns. There are various provisions as to allowances in addition to salaries—for food, sugar, laid, wood, and coal, one pair of boots a year, clothing material at reduced prices, and a lodging allowance. The Government tried to regulate the private fees of practitioners by a standard scale, but abandoned the attempt.

Hungary has four classes of hospitals. In 1921 there were 184 institutions, with 26,451 beds, 243,575 patients, and 7,342,854 days' treatment. Some belong to the State, some are "public" though not State supported, and others are private. The State is responsible for treating the indigent poor, whether in hospitals or not, and for the cost. There is a sickness insurance scheme for industrial workers and another for civil servants, but we cannot attempt to enter into details.

Notification of epidemic diseases is compulsory, but not for tuberculosis, the law prescribes compulsory treatment for venereal disease, "it is, however, very frequently impossible to enforce it."

A temperance campaign is conducted mainly by philanthropic societies which are federated into a national league. "Speaking generally, however, these organizations have not yet succeeded in obtaining any very important results." A child welfare scheme is supported by a statutory National Sickness Relief Fund. A State home is provided for neglected children. Many are sent to children's colonies. "Nine tenths of the children entrusted to the State homes are placed in families who offer every guarantee of good character." They are medically supervised. The number in the homes is stated to be close on 42,000.

Environmental sanitation as regards purity of air and soil, water supply, house sanitation, industrial hygiene, school hygiene, food inspection, and other such matters is conducted on lines more or less like those of this country.

SATURDAY, OCTOBER 3RD, 1925

THE ORIGIN OF SPECIES

It is just two thirds of a century since Charles Darwin published *The Origin of Species*, but the stimulus it gave to biological research is very far from exhausted. The main idea of the book was not new, the systematists in zoology and botany had been feeling their way towards a doctrine of evolution, and the philosophers and poets had made inspired guesses, probably the immense effect it produced was due to the fact that it presented a theory of the way in which the evolution others had suspected in the resemblances and differences of species had come about—namely, by "natural selection, or the preservation of favoured races in the struggle for life." It transcended the hints of the systematists while making the fullest use of the facts they had collected. Sir Andrew Macphail recently declared that it is a dull book, and that few persons now living have read it. He is very probably right about the number of its readers in the present day, but the ideas it contained and their popularization mainly through the opposition they excited among persons who knew little of philosophy and its history, and nothing of biology, justifies his further assertion that the controversy about evolution was the principal event of the nineteenth century, comparable in magnitude only with the controversy over Christianity in the second.

The crises, he continues, 'were somewhat similar. It was a contest between the spirit and the word. The evolutionists were not spiritual above all men but their opponents were under the strictest bondage of the letter like the Pharisees of their own book, taking their stand upon the written as opposed to the living word.' But after its complete victory with biologists, and after permeating a science even so remote as astronomy, the Darwinian theory began to suffer attacks from within the biological camp chiefly from the followers of Weismann and the mutationists. Nevertheless Mr Tate Regan, Keeper of Zoology in the Natural History Section of the British Museum, in his presidential address to the Section of Zoology at the recent meeting of the British Association, affirmed that *The Origin of Species* still remains the one book essential for the student of evolution.

The systematist—that is to say the biologist who distinguishes species—is concerned with the study of the results of evolution, and ought to have a distinct idea of what is meant by the word species, but it is not easy to find. In his attempt to find a definition Mr Regan proposes to reserve association for a collection of dissimilar and unrelated organisms that occur together, such as the animals found on a muddy bottom in the North Sea, or the plants of a range of chalk hills, and to apply 'community' to a number of similar individuals that live together and breed together. Species is then defined as a community or number of related communities whose distinctive morphological characters are in the opinion of a competent systematist, sufficiently definite to entitle it or them, to a specific name. The defini-

tions of subspecies and genus are on the same principle. This definition of species is not very satisfying, as it amounts to little more than saying that a species is a species, but it retains the idea of fertility between individuals as an essential part of the conception of a species, though the occurrence of hybrids is proof that it cannot conveniently be made the only criterion, for the morphological differences may be too great. In spite of the logical objection to his attempt, Mr Regan is able to show that his definition is useful in discussing the origin of species by providing the idea of the division of a species into communities, each of which may, in the process of evolution, become a species, or, at first, perhaps a subspecies.

Mr Regan, who is a leading authority on the classification and geographical distribution of fishes, draws several illustrations of his thesis from that division of the animal kingdom. His thesis is that the first step in the origin of a new species is not a change of structure but the formation of a community, which for some reason—the reason may not be obvious—acquires new habits or finds itself in a new environment, which may mean a restricted environment. The novel point is the influence of habit, or, as the point is not quite novel, it would be better to say the influence attributed to habit. It is not easy to determine the relative importance of habit and of environment, for change in the former must usually entail change in the latter also. All that can be said is that change of habit seems in some instances to have been the first thing to happen of this Mr Regan finds an example in the trout and salmon. The salmon is more highly specialized, grows larger, swims more strongly, makes longer journeys than the trout and may have evolved from it. But the young fish are very much alike. For the first two years both are called parr and live in fresh water, then habits are nearly the same but though both are eating the same kind of food—for example, both take flies at the surface—yet on the whole their food and feeding habits appear to be different. Salmon parr seek their food—such as insect larvae, small molluscs and crustaceans—at the bottom, whereas young trout subsist more on food brought down by the stream, and tend to keep more in midwater, thus the salmon parr may be hunting in a stretch of shallow rapid water while the trout parr wait for food in the quieter water just below. In their second year when both are about six inches long, they both turn silvery (smolts) and start down the river. The trout travels in a leisurely manner hanging about the estuary, and even the older fish frequent the coastal waters. The salmon smolts make down the river straight to the open sea where they grow rapidly, putting on several pounds in a year. The point here to be observed is that though the young are almost if not quite indistinguishable the adults differ conspicuously and that this difference is related to habit not environment.

The char is a fish very like a trout to look at but belonging to a different genus (*Salvelinus*) lives in the Arctic Ocean but in the autumn runs up rivers to breed in fresh water. Many lakes of Scandinavia, Scotland, Ireland, England (the Lake district), and Switzerland contain char, and apparently the char of no two are exactly alike in habits or structure, so that they have been recognized as separate species, to the undue multiplication of specific names. Mr Regan would regard them all as belonging to the same species as the Arctic char. His theory is that at the end of the glacial epoch the bulk of the char retreated northwards, but some were trapped in lakes, where they

¹ Macphail Sir A. *The Idea of Evolution: An Address to the Biological Society*. McGill University. January 2nd 1925. (Printed for private circulation.)

have continued to live and breed ever since, and to undergo evolutionary changes which are said to be clearly related to the conditions of life in their lake. If only the char in a dozen selected lakes were known there would be a dozen well marked forms which it would be convenient to recognize as species, but with hundreds of lakes and as many forms of char the convenience disappears. This case has been given at some length because, as Mr. Regan observes,

"a somewhat similar problem arises in the classification of man, it is convenient to place all the living races in one species. But if there were only Englishmen and Hottentots we should probably regard them as specifically distinct." As to why there is evolution, why in the flux of things a progress from the less to the more complicated is discernible, we have no evidence and hardly any theories. To quote Sir Andrew Macphail again,

biologists now agree to assume that the whole universe is composed of the same matter having an essential unity in spite of a diversity of elements and in similar conditions acting in the same way, thus we are to conclude that "from the beginning there was unity, uniformity, and development by a process which is not a fresh creation, but emergent from previously created forms. By this theory mind is traced back to the earliest physiological reaction."

COMPENSATION FOR INDUSTRIAL ACCIDENTS

THE almost simultaneous publication of a book by Dr. Lucien Mavet of the University of Lyons, on the compensation to be paid for partial and permanent incapacity following industrial accidents, and of the final report¹ of the committee on compensation for eye injuries appointed by the Section of Ophthalmology of the American Medical Association provokes an attempt to compare the practice of the two countries in so far as eye injuries are concerned.

It should first be said that Dr. Mavet's book is not limited to the eye, but is a ready reckoner (*barème*) to guide practitioners in estimating the compensation which ought to be paid for injuries to any part of the body.² All injuries from the skull and scalp to the feet recorded to have been sustained through accidents during industrial work are systematically arranged, and for each an estimate of the percentage of disability is given. Where there has been diversity in the estimates by various medical practitioners of the disability arising from some class of injury these differences are set out. Damages to joints are calculated out in a most detailed fashion; for example the degree of loss of flexion following injury to the elbow joint is illustrated upon a full page chart, in which useful and relatively poor positions are given in degrees and the resulting disability is related to these degrees. The same is done for every other joint. Nothing more complete could be devised upon such a plan. Among the other matters discussed are the disabilities arising from post-traumatic psychoneuroses, diseases contracted during the course of employment including tuberculosis, syphilis, diabetes, and tumours, as well as such industrial diseases as plumbism. The mode of calculating the incapacity arising from simultaneous multiple injuries and also

from successive multiple injuries, is explained, and Dr. Bubié's scheme for calculating the incapacity arising from industrial accidents following mutilations sustained in war is set out. The *Barème* is drawn up on a most methodical plan, and the degree of disability produced by any injury or combination of injuries can be estimated by reference to the appropriate page. There is the same precision that is expected in a trade catalogue of prices current.

Such a compilation, when based upon a consensus of medical opinion checked by decisions of the courts, as Dr. Mavet's appears to be, is of value to the profession in all countries. The mere classification of possible injuries is useful, since it is an indication of what is to be expected. There are, however, dangers in such a rigid table of values. Damages sustained tend to be regarded as absolute—so much for a finger tip. But this is rarely a true judgement. The damage is relative—it is so much for the finger tip of the person X, that is to say, the loss sustained must be related to the peculiarities of that person and of his work. Dr. Mavet recognizes this, and indicates that age, sex, and general state of the injured person, "and a thousand other circumstances which it is impossible to foresee" must be taken into account.

The first conclusion of the American report is that compensation should be based upon the visual efficiency of the individual. The loss of one eye where the other is good is not loss of half vision. The industrial visual efficiency of the individual is calculated on a formula to be 75 per cent. In the French scale the loss of one eye, the other remaining normal is given as 25 per cent, subject to an addition, according to the nature of the individual's occupation, up to 10 per cent. The American and French agree on basis, though the latter gives elasticity for special condition. The American report recommends methods whereby visual acuity may be ascertained in which both far and near vision are combined in the finding. It proposes standardized methods of measuring the acuity, the field, the muscle movements, and gives maxima and minima for each. It states that certain effects cannot be standardized—for example disturbances of accommodation, colour vision, adaptation to light and dark, and certain injuries to the lids and their muscles. For many of these losses the French scale gives definite percentages of disability. The American report concludes that the amount of compensation should not be computed until all known operative and medical treatment has been tried, and that three months should be allowed to elapse after the last trace of visible inflammation has disappeared. This rule should be subject to certain exceptions in sympathetic ophthalmia and cataract in interval of twelve to sixteen months is necessary. When there is evidence that vision was subnormal before the accident, compensation should be based upon the additional loss only. When there is no such evidence it should be assumed that the visual efficiency prior to injury was 100 per cent.

The dangers of a rigid scale of compensations are well shown by cases that have recently come before the Supreme Court of Minnesota.³ A man lost the use of an eye and received compensation. Later there was some recovery of sight so that he could read print in certain positions and note approaching objects. This partially blind eye was again injured and removed the second employer was thereon mulcted in full damages for the loss of the eye so that there was double compensation. Again an eye totally blind

² *Barème à l'usage des médecins praticiens pour l'évaluation sommaire de l'incapacité partielle et permanente en matière d'accidents du Travail*. Par Dr. Lucien Mavet. Paris. A. Petit & Co. 1925. 206 pp. xvii+327 21 figures. Fr. 6.

³ *Journ Amer Med Assoc* 1925 vol 11 pp 113-115.

since childhood was injured and removed, the workman secured the full statutory compensation for the loss of this sightless eye. On the other hand, a workman who possessed only one good eye lost it, and became totally blind, under the statute the unfortunate man received no more compensation than did the man who lost a blind eye! That was the effect of an melastic law.

THE SUPPLY OF ARTIFICIAL LEGS

As announced by a paragraph in the *Times* of September 5th, the Ministry of Pensions has decided to give the contract for the supply of artificial limbs in future to two firms only, on the advice of a committee whose report has since been published.¹ Although it is not specifically so stated, we understand that this decision refers to prostheses, for the lower limbs only, the supply of artificial arms probably remaining in the hands of those firms which have had contracts with the Ministry for some time past. Economy is the reason alleged for this change of policy, and it is argued that the interests of the amputee will not suffer, because the two firms in question will be able to supply each of the two types of metal limb which now answer to the requirements of most patients. We understand that the new contracts were originally submitted for tender to fourteen firms, all of whom declined them, but two of the firms, as the result of separate negotiations, subsequently entered into the contract referred to in the paragraph in the *Times*. The twelve firms who thus find themselves deprived of a great part of their business not unnaturally feel themselves aggrieved, and nine of them accordingly have issued a statement which shows it any into a *prima facie* case for inquiry. Representatives of the firms now excluded had an interview with the Minister of Pensions on September 29th, but Major Tison adhered to the course he had decided to take on the recommendation of the Committee of Inquiry and expressed his regret that any of the firms should be placed in a position of difficulty, he, however, held out no hope that the decision would be reconsidered. He added that the difficulty was created in the first place by the concerted action of the firms themselves in refusing to renew their contracts unless the maintenance and costing clauses were deleted. We are only concerned with the economic questions involved in so far as, like all taxpayers, the members of the medical profession are interested in the reduction of public expenditure, but we must sympathize with those firms who, having done good service in the past, find themselves deprived of what had become a mainstay of their business. But there is another serious aspect of this matter. The adoption of the recommendations of the committee appears to us likely to produce a state of things in which further possible improvements in details and in types will be discouraged.¹ The two firms who are, it seems, to hold a virtual monopoly will have no inducement to adopt new devices, and will naturally be inclined to continue on the same unchanging lines, seeing from the competition of others each of whom in the past has been eager to push forward any improvement which might secure an increased share of the work. The arrangements now made by the Ministry seem to us likely to put a stop to such improvements. Even if they do not have that effect, and supposing that a very striking improvement in limb-making or fitting is brought out by a firm no longer a contractor to the Ministry, how is such an advance to be made available for the disabled pensioner when the Ministry has definitely struck off the name of the proprietor of the device from its

list of contractors? Such an eventuality is by no means remote, and as the Ministry's experimental workshop has been closed, it is to private initiative and enterprise alone that we must look for future development. The committee whose report is now in question was composed of ten members, of whom six were laymen, of its four medical members one is an amputee who has no special knowledge of limb-fitting, though another has been limb fitting surgeon to a military hospital in the provinces. On the committee and among the witnesses who appeared before it the names of orthopaedic surgeons of repute and experience in prosthetics are conspicuous by their absence, although some such are understood to have been for several years the official advisers of the Ministry.

HEALTH ADMINISTRATION IN IRAQ

The report for the years 1923 and 1924 of the Inspector-General of Health Services in the Iraq Department of Public Health¹ is a document of more than ordinary interest at the present time. It records the difficulties with which the department has had to contend and the manner in which it has emerged successfully out of its troubles. Early in 1923 the efficiency of the public health services was jeopardized by a lack of sympathy on the part of the Government. A policy had been adopted by which the Government undertook the maintenance only of the first-class hospitals in Baghdad, Basra, and Mosul, specialist institutions, and a quarantine service, but left the provision of all other medical facilities throughout the country to local authorities—a policy which the health authorities, supported by the Ministry of the Interior, regarded as bound to result in almost complete disappearance of medical facilities and loss of control over the spread of epidemics. A compromise was eventually made by which the Government undertook the maintenance of the medical institutions in all parts of Iraq by means of contributions from the local municipalities. The municipalities, however, were impoverished, and when Baghdad and Mosul also failed to contribute, the revenue for health services throughout the country fell so low that the scheme had to be abandoned and the upkeep of all medical institutions was accepted as debatable against the Government. The decision to accept this financial responsibility was also greatly influenced by the outbreak of a serious epidemic of cholera, which began at Basra and threatened to spread throughout the country. The measures taken to combat it demonstrated the necessity of complete control of all medical institutions by a central health authority, and the vital importance of widely distributed dispensaries and hospitals. At the end of 1923 the number of hospitals in Iraq, excluding railway and military hospitals, was eighteen, two of the larger being in Baghdad, two in Basra, and one, the second largest in Mosul. In 1924 ten more were sanctioned. Fifteen of the principal health service posts were staffed by British officers, but in addition there are a number of posts occupied by local doctors under an Iraqi director of public health, Dr. Hanna Khayat, an able administrator who had eighteen years' previous service under Turkish rule. The present policy is to form a permanent health service of Iraqi medical officers, but there is much difficulty in finding a sufficient number of suitable candidates, although the quality of those actually in the service is good. Out of a total of 102 doctors practising in Iraq only 42 are of Iraqi nationality, the remainder being Syrians, Turks, Armenians, Greeks and Persians. But, if one may judge by the Inspector-General's report, a very efficient public health

¹ Ministry of Pensions. Report of the Committee of Inquiry on Metal Artificial Limb, with special reference to limitation of type. 1923. H.M. Stationery Office. Price 6d net.

¹ Report of the Inspector-General of Health Services for the Years 1923 and 1924. Government of Iraq. Department of Health Services. Baghdad. Government Press. 1925. (Folio, pp. 67.)

service is now functioning in the country. It is also interesting to note that King Faisal and his Government have promulgated a pharmacy law with a dangerous drug clause and corresponding schedules, full details are printed in the report. Some vital statistics of the three chief towns—Baghdad, Basra, and Mosul—are given, but owing to defective notification and uncertain census of population it would be unwise to rely on them. In other respects there is much useful information on the measures taken to prevent such diseases as cholera, plague, anthrax, schistosomiasis, malaria, and leprosy, all of which are either endemic or liable to become epidemic in Iraq.

INFORMATION BUREAUX CONFERENCE

THE idea of providing an opportunity for intercourse between those engaged in assembling and distributing information in the fields of science, industry, and public affairs has met with great success under the auspices of the Association of Special Libraries and Information Bureaux, to which reference was made in our issue of August 29th (p. 390). Sir Arthur Steel-Maitland, Bt, Minister of Labour, opened a conference at Balliol College, Oxford, which lasted from September 25th to 28th, and was attended by over 200 delegates of organizations ranging from the scientific societies and large libraries to research institutes and smaller associations of experts, in the aggregate probably representing more than half a million intellectual workers. The attendance included M. Otlet, of the Institut International de Bibliographie, Brussels, and other visitors from Germany, Holland, and the United States, and the international aspect of the subject was further emphasized by a valuable address from Professor Gilbert Murray on the work of the Committee of Intellectual Co-operation of the League of Nations. Dr. Chambers Mitchell, F.R.S., spoke on the *World List of Scientific Periodicals*, which has just been published with the help of the British Museum authorities, and which discloses the existence of some 25,000 separate journals, and for the first time gives a picture of the situation. Organization, co-operation, and the initiation of methods of exchange are obviously desirable to keep the community in touch with world sources of information of such gigantic dimensions. The problems of translation and collective abstracting were dealt with in papers by several authorities in the engineering and chemical sciences. An attempt was made to give the conference some insight into the library methods of the daily and technical press, and a series of papers were read by leading representatives of the library service departments of the three main political parties. The information sections of such Government departments as the Board of Education, Ministry of Health and Imperial Institute were described. Sir Horace Pimmett gave an account of the Co-operative Reference Library, which it is hoped to transfer from Dublin to London. Methods of filing and classifying library matter and correspondence were dealt with by several leading librarians. Miss A. L. Lawrence, Intelligence Officer of the British Medical Association, reviewed the medical interests in this field in a paper entitled "The co-ordination of medical information," which described bibliographical work in the United States of America, France and this country. Her statement was followed by some particulars by Dr. O. Kentish Wright about the organization of the intelligence service of the Ministry of Health. In the discussion the conference was asked to use any international co-ordinating influence it might have for securing a better basic comparative value in sociological data which is so necessary for the improvement of medical statistics. In this connexion special comment was made on the absence of provision for registration of stillbirths in this country.

LEFT HANDEDNESS

THE phenomenon of right- and left-handedness is of such general interest that any new light on its cause or significance is very welcome. The latest adventurer in the solution of this riddle is an American, Mr. Beaufort Sims Parson, who has written a book about it.¹ Plato believed that handedness was the result of nursing and early education, and many others have followed him. Sir Thomas Browne declared that handedness is "the result of institution and not of nature." Sir George Murray Humphry of Cambridge expressed the opinion that "there is no anatomical reason for it with which we are acquainted," and many others have accepted this position. Others agreed with Sir John Struthers that the subject "has ceased to attract the notice of physiologists only because it has baffled satisfactory explanation." Cunningham, in his Huxley Memorial Lecture, accepted the hereditary theory, and gave some examples to show that left-handedness is transmitted from parents to children. Professor Jordan of the University of Virginia, after collecting many pedigrees, concluded that the appearance of left-handedness is sporadic, and resembles abnormalities of bodily structure in its running in families, and in general conforming to the Mendelian law of inheritance. The asymmetry of the thoracic viscera gave rise to a theory that unequal weight gave a balance of advantage to the right shoulder and arm. Warlike theories have been propounded, and the necessity for protecting the heart with the left arm. More recent explanations have been sought in unequal blood supplies of the two cerebral hemispheres, or in the manner of origin of the carotid arteries or of the subclavian arteries. The discredit into which these latter theories fell led to the view that the asymmetry of manual function results directly from asymmetry of convolutional development in the two hemispheres, and Le Conte, without attempting to give a detailed explanation, simply expressed the opinion that "People are right-handed because they are left-brained." Humphry hinted at the beginnings of a new theory in referring to the correspondence between hand and eye. Others worked out the idea into a theory of ocular dominance, and to this Mr. Parson appears to lean. He suggests that earliest man, like the highest apes, sighted laterally, with either eye as needed, and, like the simians, was ambidextrous, that the fixed unilateral sighting faculty, accompanied by handedness, developed with the manufacture and intelligent use of weapons, and that in the beginning it was without any marked general bias for either the right or left side. The biological ascendancy of right-eyedness and right-handedness, he thinks, came about subsequently through natural selection as a result of one or more now obscure causes, the more likely being the advantage that would accrue to the warrior who, as he faced his opponent, carried his spear or club in his right hand, and later a shield in his left. He thinks, too, that sun worship probably had much to do with fixing manual dexterity. The theory of unilateral sighting as the cause of handedness is, he says, susceptible of proof by a simple test. The eye that fixes a given object (under conditions that enable the observer to determine which eye is fixing) will give the "eyedness and handedness" of the person under examination. He has devised an instrument for this purpose. But the test can be made without apparatus as follows. Double up one fist with the index finger pointing freely. Lift the fist above the head and imagine it to be a pistol. With both eyes open, fling the pistol forward at arm's length as though to fire instantaneously at some distant object. Now rapidly shut first one eye and then the other, and note which eye is in a line with both forefinger and object simultaneously. If

¹ *Left Handedness: A New Interpretation*. By Beaufort Sims Parson. Foreword by Harvey E. Jordan. A.M. Ph.D. New York: The Macmillan Company, 1924. (Cr. 8vo pp. vii + 185. 8s. 6d. net.)

it be the right eye the subject is right-eyed and right-handed if it be the left the subject is left-eyed and left-handed. But, alas for the theory, there are many persons who are left-eyed—that is, in the majority of the tests the left eye is the fixing eye—yet they are without doubt pure right-handed without a trace of left-handedness in their childhood or in their family records. There can be scarcely an ophthalmic surgeon who has not seen patients who complain that they are bad shots, and in whom there is found left-eyedness. They are right-handed, and can only shoot from the right shoulder, whereas, for no discoverable reason, when both eyes are open in taking aim the left eye makes the choice. These cases are sheer puzzles for which no explanation can be found, certainly none of the conditions suggested by Mr. Pearson meet this flaw in his argument.

RESEARCH DEFENCE SOCIETY

THE Research Defence Society is to be congratulated on the readability of its annual report, which, besides giving the usual information about the finances of the society and the changes in the committee, is enlivened by a few pages of attacks and counter-attacks directed towards the antivaccinists, and is adorned with a number of impressive and well chosen quotations from celebrated scientists, testifying to the advantages to be gained from experiments on animals. The society was formed in 1908, its chief object being to make generally known the value and necessity of experiments on animals and the great saving of human and animal lives already obtained by means of such experiments. It is not therefore, as sometimes is imagined, merely a scientific society: it is a national society of men and women united to promote national health and efficiency, to bring about a better understanding of medical and surgical studies, and to expose the false statements made against them. During the past year the Research Defence Society has been able to provide many lectures and debates, with lantern slides and information about scientific work. The society congratulates itself on its activity which led to the disfigurement of Lord Bimbury and Lord Lymington in the House of Lords on the occasion of the debate on the Dogs Protection Bill on March 31st. The report gives an account of the annual general meeting of the society, at which Dr. R. A. Lister delivered a lecture on "Our defences against small-pox" (reported in our issue of June 13th, p. 1100), which received so much attention in the newspaper press during June and July. The short articles on insulin and diphtheria antitoxin provide formidable arguments with which to meet the antivaccinator.

THE MEDICAL DEFENCE UNION

At the annual general meeting of the Medical Defence Union held at 49, Bedford Square, London, on September 25th, the president, Mr. Walter G. Spencer, F.R.C.S., in moving the adoption of the council's annual report for 1924-25, said that this was one of the most satisfactory and successful reports ever issued. The new members elected showed a striking increase, there had been very few resignations, and the total membership had reached over 12,900. The increase during the past two or three years was quite unprecedented: no doubt this was largely because the teachers in the medical schools now made a point of telling the newly qualified to join one or other of the defence societies. Everyone engaging in active medical practice should at once join a defence society, and should take care to pay the subscription each year as it fell due, if this important point was overlooked the member might find he was out of benefit when he most needed help. The work of the union had greatly increased. A number of complaints in connection with the certification of lunatics

had been successfully dealt with by the solicitors. Practitioners belonging to a defence society need have no hesitation in carrying out their duties with regard to certification. Fewer care must, of course, be exercised in such matters, but there was reason to fear that persons were being under- rather than over-certified at the present time, and this was a serious danger to society. The finances of the Medical Defence Union were very satisfactory, and the investments now stood at over £20,000. Since 1924 members had been provided with unlimited indemnity against damages and costs of the other side. New arrangements had been made by which the union was taking upon itself an increased liability in connection with the indemnity insurance, and it was hoped in this way to effect a large saving with regard to premiums. In conclusion, the president emphasized the urgent desirability of making an x-ray examination in every case of injury to a bone or joint, in this way evidence of the actual condition could be obtained in a form which a non-medical juror could understand. The annual report of the council and the financial statement for the year 1924 were adopted unanimously.

RESIGNATION OF SIR HENRY GRAY

TELEGRAMS dispatched from Montreal on September 29th announce that Sir Henry Gray has found it necessary to resign his position as surgeon in chief of the Royal Victoria Hospital, Montreal, and also as lecturer on clinical surgery in McGill University, to which he was appointed about two years ago. From the brief abstract telegraphed to the *Daily Mail* of the correspondence which has taken place between him and General Sir Arthur Currie, Principal of McGill University, it appears that Sir Henry Gray considers that from an early stage he has not had full play from his hospital colleagues. When in 1923 he accepted the appointments in Montreal he was surgeon to the Aberdeen Royal Infirmary, where he had resumed duty after acting for several years as consulting surgeon with the British army in France, in which capacity he earned a reputation as a surgeon of great independence of judgement and brilliant executive ability. His surgical colleagues in this country will learn with deep regret of his resignation from the offices he held in Montreal.

THE Harveian Oration will be delivered before the Royal College of Physicians of London at 4 p.m. on Monday, October 19th, by Sir Frederick Mott, M.D., F.R.S., on "The progressive developments of Harvey's doctrine of *Omne vivum ex ovo*."

THE David Lloyd Roberts Lecture will be given by Sir Arthur Keith, F.R.S., in the Robert Baines Hall, 1, Wimpole Street, W.1, on Monday, November 16th at 5.30 p.m., the subject selected being "Man's structural defects." It will be remembered that, only a few weeks before his death on February 22nd, Sir Clifford Allbutt had accepted the invitation of the Royal Society of Medicine to deliver the lecture this autumn.

A COURSE of demonstrations of specimens in the museum will be given by Sir Arthur Keith and Mr. C. L. Shattock in the theatre of the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C. On Friday, October 16th, Sir Arthur Keith will demonstrate specimens illustrating the pathological anatomy of acromegaly, and on Monday, October 19th, Mr. Shattock will deal with lips and tongue. The demonstrations, which will be held at 5 p.m., are open to advanced students and medical practitioners. They will be continued on subsequent Mondays and Fridays, and end on Friday, November 6th, when Sir Arthur Keith will show microscopical preparations made from recent cases of intestinal stasis.

Opening of the Winter Session.

THE STUDENT-HABIT

BY

SIR ARTHUR KEITH, M.D., LL.D., D.Sc., F.R.S.,
F.R.C.S.

CONSERVATOR OF THE MUSEUM AND HUNTERIAN PROFESSOR,
ROYAL COLLEGE OF SURGEONS OF ENGLAND

Of all the men it has been my fortune to meet in the flesh Clifford Allbutt, Regius Professor of Physic in the University of Cambridge, came nearest to my ideal of the real student and the perfect gentleman. He died in February of the present year, having reached his 89th year. For seventy of those years he was a professed student, and yet at the end of his term he carried his load of learning with ease and comfort, as if it were a garment which had become part of him. He never suffered so far as one can learn from that fell disease which so often wrecks the lives of budding students, mental dyspepsia. For his brain managed its affairs as a good woman runs her household: every article admitted to his mind had first to be sampled when admitted the right place was found for it; every article admitted had to add to the efficiency and comfort of his mental household; every room had to be furnished and used. And yet at the end of a lifetime of toil—a toil which had been his constant pleasure—he still continued to make additions and alterations to his mental furniture. His mental household hit that of a thoughtful, happy, generous housewife prospered in that which it gave away. The giving away kept the rooms of his mind sweet and living.

The True Student

I have cited the example of Clifford Allbutt in order that I may make clear what I mean by the student habit. He could sit down by the hour and apply himself with a sense of pleasure to the gleaming of knowledge from the written or printed page, drinking in and assimilating facts observed or explanations given by men who had toiled in years long gone by. He applied himself with equal ease to the writings of his contemporaries, men who were still toiling in their laboratories or in their wards. Men and women who can acquire themselves thus have acquired the student habit. Of all the struggles men undertake that which ends in making the brain the willing slave of study is the most arduous. Of all mental habits it is the one most difficult to come by, and the one which is most easily lost.

Many men who are masters of research, who force secrets from Nature by experiment, who prefer to glean their knowledge at first hand (and are, I admit the rarest and highest form of scholars) often despise the habit I wish to extol—the student habit. There have been, and there are, successful medical men who turn aside from books, who leave their medical papers unopened in their wraps, who prefer to be guided in thought and action by what their fingers have felt and their eyes seen. If by neglecting the student habit they gain something they also lose much, and it would go ill with their harvest of knowledge if their successors treated them in the same selfish way as they have treated their predecessors.

I do not claim for my ideal student, Clifford Allbutt that he was a pioneer who opened up great new fields of knowledge but he attains to my ideal because he checked what he saw and what he suspected against the observations and the theories of the great minds which have paved the highways of medicine. Nature had endowed him richly, but he could never have done what he did nor been what he was unless he had acquired the student habit. I speak as an old student of ordinary ability to young students born into the same happy estate and I say that the acquisition of the student habit is one of the most valuable assets that a man or woman can carry into any line of life.

At what age Clifford Allbutt acquired the student habit I do not know but if it came to him by the age of 20 it had come in due time for with the best of students, the twentieth year is in sight before the real purposes of life dawn on their minds. Nor do I know of the struggles he went through before

the habit of study became his second nature—such biographical details are usually overlooked—but I am certain that, even in his case, there had been a struggle for for all human habits that of the student is the most unnatural and the most forced. It is a hot house plant, which can thrive only when enclosed in the glass houses of the highest civilizations.

The peoples of Western Europe produce the highest form of students the world now has, and yet the student habit is for them a recent importation. It was otherwise in the East. 6,000 years ago perhaps 8,000 years ago, young men in Babylon and Egypt were acquiring the habit, it began as soon as the human mind conceived that knowledge could be inscribed on stone or brick. If there is aught of truth in the inheritance of acquired faculties it is from the peoples of the East we should get our finest scholars, they come of long lines of descent in which study has been endemic for countless generations. It is true that amongst the peoples of the East, from Egypt to China, we do often find those who have a marvellous facility to memorize the written or printed page and yet amongst them the Clifford Allbutt type of scholar is rare, almost unknown—the scholar who assimilates what he read and makes his learning a part of his manhood.

Rural Claim

Learning thrives in Western Europe just because it has fallen on a strong and virgin soil one which has not been wasted by the exhausting crops of a long continued literate civilization. We have still in us the vitality and the energy inherent in men and women bred for life in the open air. It is because you and I have the aptitudes and instincts of our primitive forefathers so strong within us that we find it needs an effort—an internal struggle—to settle ourselves to our books of an evening. Our difficulties are even greater when the sun shines, and a longing for the open country stirs our blood. It is then that we have to struggle with the original Adam which is present to a greater or lesser degree in the hearts of all of us. English teachers beyond those of any other country, have recognized the needs of those primitive faculties which well up in the breasts of scholars, young and old, we encourage play and sports of all kinds in our schools and universities in order that the inheritance which has come down to us from savage ancestors may find vent in exercise. Golf is one means of allaying the beast within. It is so difficult for the modern student to weld the needs of our present day life to his inborn predilections. To dance, to sing or play to feast to gossip, are the outlets of the natural man ever since our distant ancestors emerged from the jungle these instinctive outlets for enjoyment have been clung to and cultivated they have come down to us in an undiminished vigour. Before the student habit can be acquired they have to be—not vanquished or eliminated—but disciplined. That is why it is so difficult to become a real student.

You will not be a student for many years before the most natural of all human appetites begins to give you concern. Among the prerogatives of life we count the enjoyment of food, we expect to eat with relish and to enjoy the results of repletion. We are not quite certain what our brain cells live on but we do know that they need very little to do the heaviest work we throw on them: the energy in an ounce of sugar would be enough. I suspect, to produce any of Shakespeare's plays if it found its way to a brain gifted as his was. Every one of us has been given the appetite not of the brain worker, but of the muscle user. The professional student in his earlier years expects to satisfy his appetite just as fully as if he were using his muscles all day in the open air and sooner or later his stomach has to pay the price of his acquired habit of study. Carlyle Darwin Huxley and Hebert Spencer suffered from this student's disease: it is true all were moderate eaters, and yet their stomachs were in a state of continual up-*start* and rebellion, nevertheless they all lived to a ripe age. Modern physiology has given the stomach a secondary place in the hierarchy of bodily organs. And yet somehow as students know to their cost sooner or later brain and stomach react furiously upon each other. It is true that we do come across eminent students who have the physique, complexion and appetite of women. They are exceptions and should count themselves fortunate.

Most of us who take to habitual study have to pay the price, and the more we give our stomachs to do the higher is the price we have to pay. To become a real student you have to be prepared to make sacrifices. For your encouragement I would say this, that I know of no student who would exchange a regulated brain for the healthy appetite of the mental sluggard.

The Potential Student

Many of us, perhaps most of us, have grown up under the belief that it is a natural thing for young men and women to give themselves to study. It is only when we approach the problem of the acquisition of the student habit from the long-range historical point of view that we see how foreign the habit is to our nature and how recently the need for it has arisen. Some can claim that their family has produced scholars, learned men and women, for many generations such are the exception rather than the rule. The majority of eminent scholars have no scholarly lineage. They come from Highland glens, Welsh hill-sides, English county villages the first of their kind, so far as they can tell, who ever devoted their lives to the cure of learning. There must be, throughout the length and breadth of our land, immense and virgin fields of untapped scholarly talent. I am not speaking now of those rarely gifted minds which can imagine things new and true, which know the way to make Nature yield up her deepest secrets or discover how to harness new forms of energy for man's benefit, but of the rank and file which make up the learned army of a country. To join that army every recruit must learn the student step—the habit of study. It may at first sight seem surprising that there should be such an abundance of potential students in a population of manual labourers. But when one looks into the quality needed above all others to make a man a master student it is no longer surprising, for we see that the essential qualification is a power of steady application in any line of endeavour whatsoever. The potential student must have method and foresight as well. Now all of these qualities—steadfastness, orderliness, and prudence—are just the qualities which our best women apply to the management of their homes. The son who would wag his head in a professorial chair wins his way there by applying to learning the same qualities that his mother brought to bear on her domestic affairs.

The Brain's Margin of Safety

When the modern student compares his outfit of brain with that which was given to his ancestor in remote times he meets with another surprise. The men who lived in Europe 20,000 years ago were just as well equipped as he is as far as concerns size and form of brain. What did those ancient hunters do with so big a brain? They had no professional examinations to pass, no briefs to master, no leaders to write, no mathematical problems to solve no ancient classic to translate, no sermons to prepare and preach. If brains were given to us merely for such purposes then those ancient hunters had somehow come by a superfluity. Brains, however, serve the needs of much more than the intellectual side of our lives, beneath the intellectual centres lie a myriad of others which subserve more menial duties—which by their exercise fill the cup of life's enjoyment. But even this explanation is but partial, the full explanation lies much deeper, and has to be sought in a strange law which regulates the construction of all living structures. All such structures have been framed on the rule which provides a large margin or factor of safety. All our organs have been built to meet not the daily routine of life, but emergencies which occur only at critical junctures. The heart, on an occasion, can rise to ten times its usual output, the lungs, if pressed, can nearly do as well. As for the stomach, the less said the better, modern civilization tends to throw an unfair burden on it. But as for the brain, the factor of safety law holds good. We have, and our ancestors had, about ten times more than ordinary occasions require, our superfluity was given us for emergency. It is just this emergency ration that the modern scholar has to depend on, and there are few if any of us who use this extra allowance to its full capacity. You may study to the utmost limit of your endurance, and by the mere act of study you may rest assured that you will do your brain no injury. Infinitely greater harm is done by misuse and disuse of the brain than by overuse.

The brains I am speaking of are not those of children—to push education upon an immature brain is cruelty. I am

speaking of the mature brain, the state reached by most of us about the nineteenth year. It is then that the brain cells have come to their complete outfit and connexions. By habitual study you may overtax your physical endurance, you may damage your bodies if you neglect to exercise them, but you will never succeed in using your brain up to its full capacity.

Warming Up and Rusting

I have said nothing about how the student habit is to be attained. There is nothing to be said, no one can teach it, there is no royal and no easy road. Each one has to come by it for himself or herself by self effort and by self application. Nor have I said anything about a matter which every student soon discovers. Our brains have moods and tempers, like horses or the engines of motor cars, they have to 'warm up' before they will run smoothly and easily. The start is always the most difficult phase to manage. And often we are uncertain, when our brains start sluggishly, whether pressure will warm them up to study pitch or whether it is wiser to lay science or stiff reading aside and take to fiction. The healing power of a debauch of fiction is often marvellous in its results. The best brains are not like cut horses which will do a turn at any hour, like racehorses, they have their times off and their times on. Therefore each student is a law unto himself.

If I have been speaking to you who have still examinations to face, I have also in mind those who have left such ordeals behind them. Sooner or later they will discover that the student habit, which is gained only by great and continuous effort, is soon and easily lost if not exercised. And they will also discover, as I found to my cost, that it is terribly difficult to get it back again. The medical man or woman who has lost the student habit has become a camp follower in the great professional army to which we should all belong if medicine is to prosper.

THE CURES OF AESCULAPIUS

ADDRESS BY PROFESSOR GARDNER AT WESTMINSTER HOSPITAL

THE introductory address at the Westminster Hospital Medical School was delivered on October 1st by Professor Ernest A. Gardner, Litt D, Vice-Chancellor of the University of London.

Professor Gardner said that the cures effected by Aesculapius, or Asclepius, as he was called by the Greeks, offered common ground for study to students of medicine and archaeology. The precincts of Asclepius on various Greek sites were admirably situated, and were suitable as sanatoriums. And it had been much discussed how far medicine and surgery were practised by his priests, at Cos, Hippocrates himself was among them. But especial interest attached to the precincts of the god at Athens and at Epidaurus, because information existed as to how they were used. Both alike had, in addition to temples and altars, porticoes especially intended for the reception of invalids, in these it was customary for them to sleep, and they were usually recorded to have gone away whole in the morning. For Athens, they had in the *Plutus* of Aristophanes a bucolic description of such a visit. The patient, who in this case was blind, slept in the portico. The god was described as going the round of the patients, when he came to the blind *Plutus*, he wiped his eyes with a napkin, and his attendant put a purple cloth over the patient's head. The god then summoned two snakes which crept under the cloth and licked the patient's eyes. Then the god and snakes disappeared into the temple, and *Plutus* recovered his sight.

The list of cures at Epidaurus, which were recorded on two great slabs of marble, were evidently a compilation, made chiefly from inscriptions on the dedications made by grateful patients, but edited and improved by the priests. There was some confusion in them between what actually took place and the dreams that came to the patients when they slept in the portico. Usually the god himself, or a sacred snake or dog, applied a healing touch as medicine, or sometimes there seemed to be surgical operations. In almost every case the invalid was said to have gone forth whole in the morning but naturally no

record was kept of the many who were not cured. Suggestion or hypnotism might well have been used in some cases, and much may be due to faith-healing.

Other gods or heroes, such as Asclepius and Iphigenia, were consulted in dream-oracles, when no doubt the dreams were interpreted by priests. Similar rites of incubation survive to the present day in Greece, notably at Ikenos, where a large number of people suffering from all sorts of diseases, blind, or lame, sleep on the eve of the festival of the Annunciation in the great church and the crypt beneath it, and usually two or three cures are announced. Thus the reputation of the shrine for healing was maintained, and the same thing probably happened at Epidaurus and at other shrines of healing gods.

THE HUMAN TOUCH IN PRACTICE

ADDRESS BY "IAN HAY" AT GUY'S HOSPITAL MEDICAL SCHOOL

THE opening address of the winter session at Guy's Hospital Medical School was delivered on September 29th by Major Ian Hay Beith, CBE, MC (better known as "Ian Hay," novelist and playwright), whose subject was "The human touch in professional life."

Major Beith began by remarking that his only qualification for addressing a medical audience was that long ago at Cambridge, he took a course in chemistry and physics. But in those undergraduate days his circle of acquaintances was largely among those who kept a skull on the mantelpiece. Just as the saxophone was distinguished above all the instruments in the jazz band, so medical shop overtopped the talk. If one of the medical friends performed the feat of passing his bones the occasion was celebrated by everybody, theological students and all. He would never forget the enthusiasm on one first evening of term when a second year man burst into the room where he was entertaining a few friends, shook Cameron by the hand—H. C. Cameron, now of Guy's—and said: "Congratulations, old man! You have got a head and neck."

By the human touch the lecturer said he meant character and personality as compared with technical knowledge and ability. Of course, the one must not be regarded as a substitute for the other. In the medical profession above all others force of character could never compensate for ignorance of one's job. There was a tendency to day to exploit the personality stunt to the neglect and detriment of real training and thorough knowledge. The art of advertisement, which had been elevated to a high and solemn mystery, emphasized personal magnetism and points of manner and bearing rather than intrinsic merit or technical quality. Yet it must be said that in the cultivation of the healing art the human touch was of incalculable importance. As much healing was wrought by suggestion as by drugs. Many a patient got well just because he believed his doctor, though one need not go so far as the man in Samuel Butler's story who chewed the prescription under the impression that it was the medicine, and was immediately healed of his malady.

Patients were divisible into three categories. First of all there were the patients who were really ill, one need not dilate upon these because they gave little or no trouble. Then there were the patients who had something the matter with them but did not believe in doctors and said so with the bluff honesty which had made the name of Englishman respected throughout the world. These people must be humoured. My dear fellow, I agree with you. You are quite right. Physics is nine parts faith and one part colouring matter. You know, of course as well as I do that you are suffering from —, here I could follow the name of an illness, preferably two longish words perhaps with a false concord then a vague scientific description and to finish a chemical formula, which need not be correct. After that this patient would get out of his doctor's hand. A man would enjoy tennis elbow if he was able, in his club to speak of my synovitis. The third class of patients consisted of those who had nothing the matter with them but thought they were going to die. These patients needed cheering up and all the technical knowledge in the world would not avail so much as a cheerful presence and a confident manner. Humanity felt for one thing above all others—the unknown. What frightened a patient most of all

was to have nothing definitely wrong with him. Once a cause had been assigned, once he was labelled in plain figures on a card, once he had something physical to hold on to, all was well. The future practitioners in that audience would be well advised to be explicit on these points, and to tell the patient something which would keep his imagination from soaring into the region of unhealthy speculation. It was a good thing to employ some mechanical analogy, to say that the accumulators wanted recharging, or the dynamo tuning up, or to say that the patient had a Rolls Royce body—it must be no cheaper make than a Rolls Royce—but there was water in the carburettor. That would cheer him up much more than the information that his malady was functional and not organic.

The medical profession was, with the possible exception of the teaching profession, the most responsible in the world. For that reason especially one might be proud and thankful to have sprung from the British race, for the men of that race possessed initiative, the habit of acting efficiently and conscientiously without supervision from higher up. The British nations were largely run by men of other ranks, as they said in the army—men who did their jobs faithfully, each in his place, and to a large extent unsupervised. The members of the medical profession were foremost among such, and bore as heavy a burden as any in the Empire. The career which the students before him had chosen might lead them to Harley Street or to the head of a great hospital, it might set them in a laboratory, tracking down a single germ, or dispatch them off to the tropics, or it might plant them down as general practitioners in a manufacturing town, where they would work eighteen hours out of the twenty-four with a large, troublesome, and for the most part unremunerative family of patients running to them for every hurt.

The medical profession is one of the few essential trades on earth. It goes right down to the roots of human existence. It is the standing army and navy of humanity. The life of the doctor is one long campaign against ignorance, cruelty, dirt, and disease. You bring us into the world. You attend us through our voyage. At any moment we may call upon you to dry dock us, or, more difficult still, to execute repairs while under steam. And when the time comes for us to pass beyond the horizon we call upon you again to assuage our suffering. To your hands we commit the innocence of our children and the honour of our womanhood, and it is the special glory of your profession that these commitments are made as a matter of course, because we know that they will never be abused. It is indeed a great tradition and heritage to which you are about to succeed.

The speaker concluded by reminding his audience of the great reputation of Guy's men, in particular for term work and *e pur de corps*.

THE annual past and present students' dinner of St Mary's Hospital Medical School will be held at the Connaught Rooms, Great Queen Street, W.C., on Monday next, October 5th, at 7.30 p.m., with Mr. Leslie Paton, F.R.C.S., in the chair.

THE prize distribution at Charing Cross Hospital Medical School will take place in the Outpatients Hall on Monday, October 5th, at 3.30 p.m., by Sir Herbert Waterhouse. The annual dinner of the past and present students will be held the same evening at 7.30, at Gatti's Restaurant, King William Street, Strand, W.C.2.

THE St. Thomas's Hospital old students' dinner will be held at the Hotel Victoria, King Edward VII Rooms, Northumberland Avenue, W.C., on Friday, October 30th, at 7.30 p.m. The chair will be taken by Mr. Samuel Osborn, F.R.C.S. The Right Hon. the Lord Mayor and Sheriffs will be among the guests. The price of the dinner inclusive of stewards' fee, is 15s., to be paid at the Hotel Victoria. Evening dress and decorations will be worn.

THE winter session of the James Mackenzie Institute for Clinical Research, St. Andrews, will be opened by the Honorary Director on Tuesday, October 6th, at 4 p.m. It is hoped that the following speakers will open the discussions on the dates indicated: Professor Lorrain Smith (October 13th), Professor Adam Patrick (October 20th), Mr. Harvey Cushing of U.S.A. (October 23rd) and Sir Leslie Mackenzie (October 27th). All practitioners are cordially invited.

GENERAL MEDICAL PRACTICE IN ENGLAND AND GERMANY

SOME PERSONAL IMPRESSIONS

[FROM A CORRESPONDENT]

ALTHOUGH, before the war, the Black Forest was as familiar to English tourists as any pleasure ground of Europe, the country east of the Schwarzwald and west of the show places of Bavaria had been less visited. Ickburg, in the Blackgau, calls up pleasant experiences to thousands, of whom not ten had penetrated some hundred kilometres to the east, to the little town of Sigmaringen, a name which, for a few days, fifty-five years ago, was in every newspaper. Situated on the upper Danube, near its most beautiful reaches, Sigmaringen had claims on the attention of the holiday maker which Germans themselves sufficiently honoured. Foreigners, however, were few—even if they included very excited visitors, for the princes of Hohenzollern-Sigmaringen, although no longer reigning princes, kept up a regal state in the Schloss.

The town, therefore, had none of the air of a tourist resort, neither was the conventional adjective "unspoiled" appropriate. It is true that the Schloss, some 700 ft above the river, and the Marktplatz, with its cluster of steep-gabled seventeenth century houses, recall a dozen "unspoiled" towns in the kindly land of Swabia. But what really characterized Sigmaringen was not architecture of the seventeenth century, but the long main street of great buildings all less than a hundred years old, and nearly all government offices. For Sigmaringen was the administrative headquarters of the province of Hohenzollern, which is rather larger than our county of Huntingdonshire, and, being in Germany, needed many more civil servants and local officials than Huntingdonshire employs even now.

Perhaps the government buildings in Sigmaringen were not really so large as the public offices in Whitehall, but in this quiet town, they seemed more imposing, with their handsome portals and trident-looking eagles (Hohenzollern is administratively part of Prussia). "Königlich Preuss Oberamt I," in large capitals, is more inspiring to the foreigner, than, say, "Home Office" in small letters.

It was a town of civil servants, wherein the conditions of social life were perhaps more similar to those of an official centre in British India than to what we find in a small English provincial town. Official rank (in the civil service, there were no soldiers) counted for much more, and wealth for much less, than in an English country town.

Such were my recollections of the town in 1912, when I was last there, returning last month, I wondered what changes the war had made in this quiet place.

Outwardly, there was little change. The public parks were not quite so tidy, the buildings were not quite so sprick and span, the impression of order was not quite so impressive. "Preuss Oberamt I," with a faint discoloration to the left (where the "Königlich" had been obliterated) seemed lop-sided. But it was still an official town. Indeed, there were more officials than ever, for a huge military training college, which had just been finished in 1912, contained no soldiers, but had been converted into a training office, with a new and large staff of civil servants. England is not the only country that has increased its civil establishment since the deluge.

Quidquid delirant reges plectuntur Achivi.

For reges read ex-Kaiser Wilhelm and his like in other lands for Achivi read the professional middle classes in every land and one has a universal after-war truth. I was interested to learn how our subdivision of the Achivi the medical profession, had fared. The friendship of two practitioners in the town enabled me to form impressions (of course, mere impressions, I have had neither leisure nor much inclination to modify them by study of documents) which may interest other medical men. Before describing these however, one must notice some general characteristics which affect the middle classes as a whole in the two countries.

In the first place, the levels of retail prices. From the merely arithmetical point of view, it is much easier to compare the price levels of the two countries now because, since the stabilization of the exchange, the rentenmark is practically equivalent to the English shilling. At present the retail purchasing value of the rentenmark is almost the same as that of the shilling. The German retail price index number is indeed slightly less than our own index number (which on July 1st was 73 per cent above the pre-war norm), but as the index numbers are not constructed in precisely the same way, accurate comparison is impossible. Food and tobacco are cheaper, good clothes much dearer, rent rather dearer than in England. We shall not be very far wrong in saying that in both England and Germany £100 now buys little if any more than £60 would buy in 1914.

So far, it is a case of "all square." But the depreciation of savings has affected the professional classes very differently. Take first our own position. The savings of a moderately prosperous, reasonably cautious, English doctor would, I think—of course, I am judging from the narrow experience of my own English circle—take the form of (1) a life assurance policy, (2) investments in solid securities either gilt-edged or just below gilt-edged, which before the war did not yield above 4 per cent on the investment. I think such a man acted on the assumption that an effective yield of more than 4 per cent and safety were incompatible. In 1925 the rate of interest of securities of this class is about 5 per cent. For instance, in the *Times* the 5 per cent War Loan is quoted at 101½ and the highest and lowest prices in 1924 were 101½ and 98½. Great Western 4 per cent debentures are 81½, 5 per cent debentures 98. It follows that anyone who invested £100 in a fixed interest bearing stock returning him 4 per cent on his capital in 1912 will be able to sell it for only 80 per cent of what he paid. With this amount he will only be able to buy commodities which could have been had for £48 in 1912. The same argument, of course, applies to the capital value of an assurance.

English savings in the professional class—the safe investments—have therefore depreciated to the extent of one-half. If, as happened to many doctors the investor was obliged to realize three or four years ago in order to purchase the house in which he lived and practised, the loss was a good deal more. It is certainly not putting the loss too high to call it 50 per cent. This fact was new to my German colleagues, who still entertained the traditional belief that all Englishmen are very rich. But they have this excuse, that the savings of the German professional classes have depreciated much more than 50 per cent. It is not technically correct to say that all investments in first-class German securities (Government loans etc.) are worthless. The State may resume the payment of interest and may refund as much as a third of the capital many years hence. But I did not gather that anybody expected to receive a rentenpfennig after any number of years, and nobody can receive anything now. The position of policy holders is illustrated by this example. A civil servant in the town held for many years a life policy for 20,000 pre-war marks. He died after the introduction of the rentenmark, and his widow received from the company 20 rentenmarks. An English doctor who insured his life for £1,000 in 1912 will, if he dies to-morrow, leave his widow about as well off as if he had insured for £450 to £500 and there had been no war. His German colleague's widow will get £1.

To measure the importance of this in comparing profession with profession in a statistical way naturally requires a knowledge of the average ratios of savings to gross income in the two countries. But, putting the case at its lowest, supposing that in neither country has it been within the capacity of the medical profession to save much the moral effect of the position is very great. In the middle class, doctors included, the bitterness of feeling engendered can only be realized if one mixes on friendly terms with our social and professional "opposite numbers."

Passing to the conditions of general practice one notes that in Germany, as in England, the system of National Health Insurance is the dominating factor. The regulations in force in the two countries are far better known to many English doctors than to me, whose knowledge,

indeed, of English conditions is not based on recent personal experience. I confine myself to the impressions gained in one town, which is, as I have pointed out, of a special type.

While in England the method of payment by capitation grant is the usual plan and payment for work done the exception, the position in Germany is reversed, and the profession much prefers the method of payment for work done. In an area not far from Sigmaringen the capitation system—the rate being 5s per head per annum—is in force, but I did not obtain any details of its administration. In Sigmaringen itself the method of payment is 1s for each consultation in the practitioner's house, 2s for each visit within a minimum distance, and a kilometre allowance for distances in excess of the minimum.

The system works in this way. Any qualified practitioner entering a district can apply to have his name entered on the panel of insurance doctors (*Kassenärzte*) and, although powers exist to close the list if the supply of practitioners be deemed adequate, the application is normally granted after a residence of six months. Insured persons have complete freedom of choice. Thus, suppose in a district there are four *Kassenärzte*—Drs A, B, C, and D. Hans Schmidt is an insured person, and decides to consult Dr A, who sees him three times in his consulting room and twice in his home. Dr A will be paid 7s—1s for each consultation and 2s for each visit. If Hans does not like Dr A's manner or the medicine he prescribes he can, when he is ill again, consult Dr B, Dr C, or Dr D without any formality. He can, indeed, go from Dr A to Dr B in the same illness, but, in that case, some person must be assigned. How this proviso actually works can be illustrated by an extract from a little volume of sketches of medical life by Dr Max Nassauer.¹

Dr Fellner has been treating me for three weeks. began a shabbily dressed middle-aged woman in Dr Fuchs's surgery house. Her voice had that touch of arrogance which distinguishes the voices of people who think they are important. He doesn't understand my case, she went on, he comes and sees me every day but I am not getting any better. Now you have been recommended to me. I am the housekeeper at the Palais Ohrenberg so of course I am in the insurance. "Yes, Mrs. —."

"So I have come to you," she interrupted. "We have paid insurance money for years. So you will be paid!" Quite so, madam. Dr Fellner who has visited you every day for weeks. He too madam receives a few marks from the Insurance Committee perhaps to pay the train fares to your house. How ever if you have no confidence in him I will treat you. But you must first tell him that you have come to me before I treat you.

The housekeeper sends for Dr Fuchs late in the evening. She is half an hour from his surgery and Dr Fuchs would like to have supper but he must postpone this for a doctor's dinner matter. His wife and child have supper by themselves. There is nothing really wrong with the housekeeper. But after all the Insurance Committee pays the doctor and it is much pleasanter to have supper comfortably with one's husband and then send for the doctor.

The husband begins. We have telephoned to Dr Fellner that he needn't come any more. Let us hope he shrugged his shoulders.

The pecuniary side of the work, how it compares with English experience, can be judged better by my readers than myself, I can only add the following items which are relevant.

Competition is at least as keen as in England. In Sigmaringen, without counting the *Geheimer Medizinalrat*, an official not seriously engaged in private practice, or the director of the hospital, there are seven medical men. The average for the first ten English country towns of approximately the same size in the current *Medical Directory* is six.

Strange as it may seem at first sight, the proportion, always high of men who pass through the universities has greatly increased since the war. The universities are overcrowded although the severity of the academic tests has been increased in all faculties and the proportion of "ploughs" is high. Many explanations have been given. One is that with the abolition of the military caste the social prestige enjoyed by a *Gebildeter*—always much greater in Germany than in England—has no longer a military rival. A more probable reason, as I think, is the unconscious faith of Germans that in education, and education alone can the nation find salvation. However this may be,

there is little doubt that the supply of doctors of all faculties is at the least equal to the demand.

Average incomes are misleading, like most averages, unless one knows how they are compiled, so I do not quote them. But it is instructive to know what sort of an income is regarded as enormous. One of my friends remarked that he had heard of cases where one or two men—"insurance lions" he called them (*Kassenlöwen*)—had actually reached a gross income of £750 to £1,000.

Lastly, my friends had no doubt that, whatever its drawbacks, the insurance practice was the principal means of subsistence. When one remembers the general situation of the middle classes it is indeed fairly obvious that medical practice in the social class above the insurable limit cannot be remunerative.² As I have said, the significance of all this will be more correctly estimated by experienced practitioners than by me. This at least was obvious enough, that the doctors in Germany whom I knew had an appreciably smaller share of the physical comforts of life than those of my English friends whom I judged to occupy an equivalent position socially and professionally.

There were some other differences between German and English professional conditions which interested me. I have heard it said that one of the results of our English system has been to strengthen vested interests and to make it more difficult than it was a generation ago for a young medical man without capital to start in independent practice—in other words, that here the advantage is more with the older men and established firms than it used to be. I do not, of course, know whether this is true, but if it is the position is quite different in Germany. The older men complain that they cannot live owing to the competition of the young. Two reasons seem of importance: (1) the absolute freedom of choice of doctor, so that the patient can pass from one to another doctor without any formality whatever; (2) the fact that medical partnerships are unknown. The position of a doctor getting on in years with no son in the profession, and his savings rendered worthless, is a gloomy one indeed.

In Nassauer's book, from which I have quoted already, there are bitter complaints of the demoralizing effect of the insurance system from the professional point of view. I will quote one more passage, from a sketch entitled "The Serf."

It was striking 11 as Dr Metzler came back. Just as I told you he said brushing the snow from his beard. And when I told them the man was merely drunk they simply eased me and wouldn't believe a word. The wife shouted after me that she would bring the insurance book round in the morning for me to certify her husband for sickness benefit for he was quite unfit to work. Sickness benefit indeed! How these insurance laws have demoralized the people! Tomorrow he will come along and whine that he has pains all over and can't work and beg me to give him a certificate. If I find nothing and refuse to sign him up he will swear at me probably there will be an article in the paper about my hardness of heart and inhumanity and the man will go round until he does find a doctor who will do what he wants. And many of his friends and fellow workmen will not come to me again because I am too straight. If I do sign him up because perhaps after all there is a grain of truth in his complaints and the insurance committee has him examined and find nothing wrong then I shall have my nose bitten off.

These complaints and complaints of lay treatment, of end less boot keeping—"if our legislators only knew how they have degraded the scientific level of medical work, forcing us to this mass production, perhaps there would be a change"—have been heard in England. It seemed to me that my medical friends emphasized more the tyranny of the local committees and less the interference of officials of the central Government than English critics do. But at least all the grievances felt in England are well known in Germany.

One other point struck me—the intense bitterness with which my friends inveighed against the evils of quackery, the tremendous competition of the charlatan and patent medicine vendor. Nassauer's book is full of this, and it is a little surprising to the Englishman who thinks of Germany as the land of *verboten* to realize that illegitimate practice there is as formidable an enemy as in England.

Such are the scattered impressions of medical life in Germany which I gathered. They can only be gratifying to

¹ *Die Diktorskule* (München 1925 Gmeln). This humorous and pathetic book which my German friends assure me is true to life deserves to be translated.

² This would no doubt be especially felt in a population of civil servants with a number of pensioned officials.

more robust hters than I am. I suppose most Englishmen who can speak French and German fairly well would agree that, in spite of all that has happened since 1914 one is much less reutely conscious of being a *foreigner* in a German middle-class environment than in a French one. Indeed, this sense of homeliness is rather stronger than before 1914, because officers in uniform can no longer be seen in Germany. My impressions may perhaps give food for thought to those who denounce the condition of our own country.

Correspondence.

TUBERCLE-FREE MILK

SIR,—A case recently under my charge presents some points of interest from a public health point of view, and suggests some questions.

On September 3rd I was asked to see an only child, a boy, aged 2 years and 2 months sent by Dr G F Campbell Bangor. His mother gave the following history. He had been breast fed for six months and all the milk he had since received prior to June 1st had been tubercle free from cows tested by tuberculin. On June 1st he went on a holiday with his parents to a place where ordinary milk only was available for his use. On July 20th he was taken suddenly ill. He complained of pain in the right side of his neck, which was very considerably swollen. The swelling was tender but not red and the temperature was then 103° F. and for ten days ranged from 100° and 103°. He had no sore throat though there was a very slight enlargement of the right tonsil as compared with the left. When I saw him on September 3rd his general condition was normal with the exception of considerable enlargement of the upper deep cervical group of lymph glands.

On September 13th I removed the affected glands which had in the meantime become softer though the skin was not red and there was no fluctuation. The operation was much more difficult than usual owing to the amount of periaadenitis the knife and not blunt dissection being necessary throughout. The glands were subsequently sent for examination to the Pathological Laboratory, Queen's University and Dr Ori has reported to me that he has found with considerable ease tubercle bacilli present in the glands.

The points in this case are (1) The child had been fed until June 1st on tubercle-free milk. (2) Seven weeks later there was a considerable enlargement of the lymphatic glands of one side of the neck. (3) These were found on re-examination to contain tubercle bacilli.

Such are the facts, and the questions suggested by them are (1) Can one assume that infection occurred from milk during the seven weeks in which the child was taking ordinary milk? (2) Has this infection anything to do with the fact that he had previously been reared on tubercle-free milk?

Definite answers to these questions cannot I think, be given, but it would be interesting to know from your readers whether similar cases are occurring, the supply of tubercle-free milk being now advocated by the medical profession. It would be important to know whether in present circumstances this affords a real safety or whether it continues as well a lurking danger for the child who has hitherto acquired no immunity to tuberculosis. The acute symptoms, the periaadenitis and the finding of tubercle bacilli with ease in the glands would seem to indicate that such a danger requires recognition.—I am, etc.,

S T IRWIN

SYPHILITIC NEPHRITIS

SIR—In his interesting paper on syphilitic nephritis in your issue of September 26th (p 551), Dr G B Dowling states that he has only been able to find two cases described in the literature which responded to treatment in the same way as that recorded by him. I recall two similar cases at Guy's Hospital the first being under the care of Dr Newton Pitt, when I was his house-physician in 1905, and the second under my care in 1912.

The former was a woman who had been in the hospital for about twelve weeks in a waterlogged condition with a very large quantity of albumin in her urine. Her condition was getting slowly worse, and it seemed unlikely that she could survive much longer when she developed a rash on her face, which Sir Cooper Perry diagnosed as syphilitic. This was before the days of the Wassermann reaction, but she was at once given potassium iodide. Within a week the

oedema and ascites had disappeared and the urine was free from albumin. Shortly afterwards she was discharged from hospital apparently cured.

The second case was clinically almost identical. After being ill with severe oedema and abundant albuminuria for about three months, she complained of vulval soreness, which Mr Bellingham Smith found was due to the presence of condylomata. The Wassermann reaction was positive, and she was given a mercury and iodide mixture, with the result that in four days the oedema was gone and the urine was normal.

Cases of this kind must be very rare, because, having observed the extraordinary recovery of these two cases, I have the Wassermann reaction tested in every case of nephritis I see, and only on one other occasion has it proved to be positive. This was in a man of 51, who had contracted syphilis when 20 years old, but had never received any treatment for it. Fifteen years later he developed severe nephritis with abundant albuminuria and severe oedema. He was given a very bad prognosis, but survived for twenty years, living a useful and very active life in spite of having oedema of his legs, scrotum, and face in varying intensity the whole time. When I first saw him in 1921, four years before his death, he had 30 parts of albumin per 1,000 in his urine, with a few hyaline and granular casts, the blood urea was 0.16 per cent—well below the normal maximum—but the urea concentration test showed some renal insufficiency. The systolic blood pressure was only 130 mm, and there was no cardiac hypertrophy. The condition was complicated by the presence of pneumonia, due, apparently, to infection of his bladder with Welch's bacillus. Some improvement followed vigorous antisyphilitic treatment, and he remained active till a very short time before his death, though in 1923 albuminuria reinitis developed, and this finally made him almost blind. His history shows that even in the absence of treatment syphilitic nephritis has an exceptionally good prognosis, as it must be very rare for a case of chronic nephritis with severe oedema and abundant albuminuria to live an active life for twenty years without any rise of blood pressure or cardiac hypertrophy, and without developing reinitis until two years before the end.—I am, etc.,

A FRENCH VIEW OF FREUDISM

SIR,—If your reviewer is to be trusted, as one cannot doubt, Dr Laumonier's "exposure" of Freudism (*Le Freudisme Exposé*) shows that, like so many other critics, he has completely failed to comprehend the theories he attacks. This would not in the least matter were it not that your lengthy notice of the work (September 19th, p 519) may lead the many into thinking that by Freud receives a "knock-out" blow. It is really ludicrous to attribute to Freud the idea that children experience sexual emotion on an adult plane, and yet the main attack of this French critic is based upon this fantastic notion. It is unnecessary to repeat here what Freud's views really are on the subject of infantile sexuality. The English translations of his works are available and in both his *Introductory Lectures* and *Collected Papers* the subject is treated with a clarity which should place it beyond misrepresentation. One cannot think either that Freud's definitions of his terms "unconscious" and "pre-conscious" are in any way lacking in precision.

However, my main object in writing is not to contest the article point by point, but to emphasize the harm done by the assumption that the whole question of a dynamic unconscious stands or falls by the validity of Freud's views on the evolution of the sex instinct. Such an attitude towards psychology provides a stumbling block at the very outset, with the result that the majority of the profession refuse to consider modern psychological teaching at all. In a recent letter to the *Lancet*, I deplored the lack of facilities for the medical student to acquaint himself with the fundamental principles of psychotherapy, and I should like to labour the point again in this the sister journal. There is sufficient common ground between McDougall,

Rivers, Adler, Jung, and Freud (to mention only a few of the outstanding names) to provide a solid basis for the understanding and treatment of neurotic conditions, and the dust of conflict can be ignored.

No one can pretend that the neurotic patient at present receives anything like adequate treatment. The public facilities are all but non-existent, and few private practitioners have either the knowledge or inclination to deal with them. The resulting economic loss to the community must be enormous, and if further generations of students are allowed to enter practice knowing nothing of the origins and treatment of the functional disorders with which they will be brought in contact every day, the outlook is hopeless indeed—I am, etc.,

Birmingham Sept 21st

R MacD LADILL

APERIENTS FOR ABDOMINAL PAIN

SIR,—Pace Mr Flint (September 19th, p 540) the vast majority of acute abdominal pains in children are not due to appendicitis, organic obstruction, or other serious conditions, and, though "a good clean out" may not be all that is required, it is undoubtedly the most essential precursor of relief, as a rule there is no relief until it occurs. The surgeon does not see these cases, and even the general practitioner sees probably only a minority of them, and "out of sight is out of mind." Mr Flint's dictum, that "it is dangerous to give aperients for acute abdominal pain without the sanction of a doctor," takes no account of the vast majority, and if his advice were generally adopted innumerable children would have their sufferings unnecessarily prolonged, though possibly one here and there might be saved a little suffering and perhaps some danger to life.

On balance I think much more harm than good would accrue from the adoption of the advice, for, failing "the good clean out," a certain number of benign conditions are apt to take bad ways and become serious. In organic obstruction aperients increase the suffering and, if repeated, may turn the scale against recovery, and the same holds good for a few other comparatively rare conditions, but in incipient appendicitis it is quite rational to suppose that an aperient, by unloading the caecum, may have a favourable effect, even if it fails to abort the trouble. To hold an aperient, given during the first few hours of an attack, responsible for subsequent gangrene, suppuration, or perforation, seems to me quite irrational, a loaded caecum, left loaded, seems much more likely to produce such results, and I should say (submissively) that such results seem quite as frequently when aperients have been withheld as when they have been given early. Some cases are doomed to gangrene or perforation from the outset and are hardly influenced for good or evil by anything short of surgery.

In industrial practice the doctor seldom sees these cases until the second day (and often later) and by then the time has passed for the administration of an aperient if the case is appendicitis, though theoretically in a few cases an aperient might still act favourably. Practically few of us are capable of diagnosing the exact condition of the appendix and surrounding parts, and so we are wise to take no risk. It is by no means unusual for cases seen on the second or third day to present a history and a few indefinite physical signs highly suggestive of an attack of appendicitis which has been cut short and if an aperient has been given at the outset (and has acted well) the doctor, as well as the mother, may be forgiven for suspecting that the aperient was beneficial, obviously it did no harm. If the industrial population could and would send for a doctor (and get him) at the very outset of abdominal pain, the onus of giving, or withholding an aperient would be on his shoulders, and a few disasters might possibly be avoided, but a good deal of broadcasting would be required to produce such an ideal, and in the meantime many mothers, acting on Mr Flint's dictum, would withhold the necessary aperient for a much longer time than is desirable in all but a very small minority of cases.

Hard cases make bad law, and it seems unwise to make a well founded faith in the efficacy of aperients for abdominal pains generally because in a very small minority of cases they may do harm—I am, etc.,

Swinton S pt 26th

J PRICE WILLIAMS

MEDICINE AND THE PUBLIC

SIR,—Mr L. R. Flint's letter in your issue of September 19th is both timely and interesting, especially as a sign of the times, and in the light of the Royal Commission on National Health Insurance, which (among voluminous other recommendations with regard to the National Health Insurance Act) is considering the scheme for national medical service published in the *BRITISH MEDICAL JOURNAL* of April 20th and May 4th, 1912, and subsequently in my pamphlet *A National Medical Service*, after consideration and agreement thereto of the Manchester (South) Division of the British Medical Association on May 3rd, 1912.

Returning to general practice here after an interval of ten years (away at the war and in the Colonies) I am struck by the fact that, as Mr Flint writes, "the patient does not give his doctor a fair chance" nowadays. As Mr Flint truly remarks, "it seems a calamity that elementary knowledge of an official kind should be withheld from the public, while pernicious statements on behalf of quack remedies are allowed to be published wholesale." Surely the Royal Commission should recommend either the total abolition of quack remedies, or that a statement of the actual ingredients and their quantities must appear on the labels.

In 1912 the late Dr Rentoul of Liverpool published a pamphlet pointing out that as far back as 1889 he "proposed the formation of a public medical service. The doctors refused it, because they thought it would affect their money interests. But had they accepted it, we would not now [1912] be like mendicants with hunched knee waiting for charity rates of pay to be offered us by politicians."

My proposals for a national medical service were put forward when the National Insurance Act was being considered, and now the borough of Teddington is putting practically the same scheme into operation experimentally as a voluntary service scheme, which should be watched with the greatest interest by the whole medical profession in general and the British Medical Association in particular, as well as by the Royal Commission itself. In a further pamphlet, just published, I have set out in tabular form a comparison between the Teddington voluntary scheme and the national medical service I proposed to Mr Lloyd George at the time of the consideration of the Insurance Act. Mr Flint's opportune letter points to the inevitable formation of such a national medical service. The time for individual spirit from collective private practice has long gone by, and the danger of a C3 population was never so threatening as now.

Every argument used by Dr Rentoul and many others in 1889, by myself and others in 1912, and by Mr Flint now, could be used to day with sevenfold power and force by anyone who knows the conditions now and can compare them with those before the war both in private and hospital practice. It is time we organized to form the best national medical service in the interests of the highest traditions of our profession, as well as in those of the people we exist to serve. To all who are interested I would be pleased to send a copy of my 1925 pamphlet and to correspond with them to help forward what is now seen by all, I believe, to be the orderly evolutionary and not revolutionary development of the medical profession in the interests of the national health—I am, etc.,

MILSON RUSSEN RHODFS

Leicester Sept 21st

SEA-WATER FOR SEA SICKNESS

SIR,—A note in your issue of June 20th about the oral administration of a 2 per cent solution of sodium chloride as "a remarkably satisfactory treatment for vomiting in shock" recalled experiences in treatment with sea water.

In January 1901 while on the ss *Cornwall* with the Sixth New Zealand Contingent en route from Auckland to South Africa, Sir Owen Cox the manager of the Federal Shipping Company, who accompanied us as far as Sydney, told me that a good dose of sea water was the sailors' remedy for sea sickness. Consequently when after a further six days at sea as many as sixty-six men paraded sea sick hoping for medicine and no duty. I had a Winchester bottle filled with sea water labelled *Mistura Oceani Pacifici* and prescribed half a tumbler to be taken statim. It was interesting to note the effect on some it acted as an emetic,

on others is an aperient. As to its efficacy, suffice to say that on the following day only four paraded sick. It is only fair to mention, however, that we were to go ashore that day at Albany, Western Australia.

In 1910, while voyaging from Hobart to Hell's Gates, Strahan up the wild west coast of Tasmania in passing Port Davey, where the wind was contrary, two cabin companions both in the throes of sea sickness made a piteous appeal for something to relieve them. Half a tumbler of sea water followed later by a brandy and soda brought them to dinner.

My last experience of the use of sea water for sea sickness was on H.M. transport *Minneapolis* on the day of the Anzac landing. As I was about to take the morning sick parade a South Australian lieutenant of artillery, obviously with a dark brown 'taste' in his mouth on the morning after the night before said: 'Doe send me a dose of Enos's fruit salt.' Taking neither the abbreviated title nor the idea of auto-prescribing, I sent a tumblerful of sea water with the doctor's compliments. The gallant lieutenant appeared at breakfast but was solicitous to know if it were actually Enos's which he had taken. On being answered in the affirmative he remarked that it must have been old stock as it did not fizz and had a musty taste. He admitted, however, that it had fixed him up all right. Later in the day he approached me again, saying 'Fair dinkum! Tell me was that really Enos's fruit salt?' Ultimately when he was again feeling agreeable I told him that he certainly had been cured with Enos's salt as at the time we had been passing through the Gulf of Enos he had drunk thereof.

While at Alexandria, in 1915, I tried washing out chronic cases of urethritis with sea-water, with apparently some improvement, but my transfer to Cairo, as specialist sanitary officer, cut short further opportunity for experimental therapy. Dr. Wiley of Sydney, however, tells me that at the Australian V.D. Hospital at Bulford, Salisbury Plain, in 1917, sea-water was also tried as an injection, but did not seem to have any advocates. There is, however, a sphere for the use of sea water which, as the result of experience, one can commend. Observation in times of influenza epidemics that habitues of snuffing did not suffer, and knowing that a solution of sodium chloride is a favourite application to mucous membranes, I have advocated the snuffing of a little sea water up the nostrils each morning as a prophylactic against catarrh. Those who have once used this hypertonic saturated salt solution discard thereafter nasal douches of antiseptics and other so-called prophylactics, whose name is legion, for nasal catarrh.—I am, etc.,

MULTIPLE NEURITIS AND FATIGUE

Sir,—In view of the very interesting contribution of Dr. W. Johnson (Liverpool) to the discussion on multiple neuritis, at the Annual Meeting of the British Medical Association at Bath (BRITISH MEDICAL JOURNAL, September 12th, p. 466), perhaps an extract, which I take the liberty of quoting, from my thesis on "Lead paralysis," written twenty years ago, may be of interest.

In the production of this condition the element of fatigue seems to me to take an important part. From a comparison of the following cases it will be seen that that arm which had the hardest work to do was primarily and most seriously affected.

(Case 1)—By occupation a tile scraper. In this she was constantly scraping the tiles with a knife in her right hand, whilst thus working she kept her right hand cramped for an hour or so at a time her wrist incessantly undergoing flexion and extension. Her left hand though being used was allowed some rest between the picking up of each consecutive tile. In her case the right arm was the first to be affected and remained permanently the worst of the two.

(Case 2)—A myroloka kiln placer. His work was to fetch the tiles from the dipper and place them in the myroloka kilns. The right hand was almost entirely the one used the right wrist dropped first and recovered last.

(Case 3)—A ground layer. The ware was supported by the left hand whilst the pencil was being constantly applied with the right which was primarily and more seriously affected. [Several other cases were recorded to illustrate the point.]

In muscles having undergone much exertion there is an absorption into the blood of waste products that temporarily poison the system. These act upon the nerve endings in muscle and temporarily paralyse them due to the nutrition of the nerve fibres being lowered and therefore they are unable to resist the absorption of poisonous products.

Since in lead poisoning metabolism is so much affected and the action of the liver, kidneys, skin and bowels is imperfectly performed it is not possible that the toxic products of lead circulating in the blood act in this way on the nerve-endings of fatigued muscles and paralyse them?

'It seems likely that at the end of a hard day's work in some lead occupation absorption of lead is more probable than at the commencement of the day when the tissues are invigorated and that therefore the element of fatigue may be a factor in the production of such poisoning by acting as a predisposing cause to the toxic effect of lead.

The fact that women are more susceptible to the poison and so to the paralysis may be due partly to their inferior muscular development and consequently fatigue is more readily produced, the muscles at the same time losing their tone due to want of trophic influence which cannot be supplied from the chronically inflamed nerves.

—I am, etc.,

Bath Sept 14th

H. CLULOW NIXON

VENEREAL DISEASE IN THE NAVY

Sir,—In your issue of September 19th (p. 524), commenting on the statistical report on the health of the Royal Navy for 1922, you make a laudable comment on the obvious failure of the naval medical authorities to enforce observance of prophylactic precautions against venereal diseases. A hospital admission rate of 282 per 1,000 among men on the China Station is difficult to account for otherwise than by indiscipline on the part of the men and laxity on the part of the medical officers.

More serious, however, is a menace to public health at home in the statement that large numbers of men are being discharged from the navy on account of gonococcal infections. These uncured cases should surely be retained in the service, where, as the men are compelled to undergo treatment, ultimate cure can be more readily achieved. As a civilian clinical officer, one can sympathize with the naval surgeons in their disinclination to go on treating difficult cases of chronic gonorrhoea, but one cannot condone the Admiralty's total disregard of the consequences to the health of the civil community.—I am, etc.,

Glasgow Sept 24th

ROBERT FORGAN

POSTURE IN BRONCHIAL AND TRACHEAL DRAINAGE

Sir,—The instructive letters of Drs. Eve and Neild on posture for bronchial and tracheal drainage have drawn attention to an old but somewhat neglected method of treatment. Sir William White, in his *Dictionary of Treatment*, states:

A point of primary importance in the treatment of all cases is to educate the patient systematically to assume such a position as will upon coughing enable him to empty the cavity by the force of gravity. This he may do lying in bed and almost inverting his body supported by his hands placed on the floor whilst his head is lowered almost to the level of his hands.

Over thirty years ago, as an old pupil, I attended a clinic of Sir William's—then Dr. Whittle—on the treatment of bronchiectasis and allied conditions, in which the postural treatment was discussed and the various methods, such as bed rests, pillows, and so on, were exemplified.—I am, etc.,

Pendleton Manchester Sept 16th

S. McNair

Obituary

THE death is announced of Dr. WILLIAM MORRISTON DAVIES, formerly of Gordon Square, London. He was educated at Edinburgh University, where he graduated M.B., C.M. in 1873 and M.D. in 1878. He took the diploma of L.R.C.P. Ed. in 1872. He had served as surgeon to the Huntingdon County Hospital and physician to the Medical Mission Hospital, Edinburgh, and was the author of a work on *Hæmorrhoids: their Pathology and Treatment*. Dr. Herbert Spencer writes: 'The death of Dr. Morrison Davies came as a great shock to his friends, of whom I have been one for the last forty years. Dr. Davies had reached the age of 83, but he always seemed twenty years younger than his age, and, long after he was 70, I have seen him climb trees with the agility of a monkey. For many years he had a large practice in Gordon Square, and his care and devotion endeared him to his patients. After his retirement from practice he bought the Manor House, Stoke Poges, a sixteenth century building and the home of Penn, which Dr. Davies restored with the finest taste and fitted with the exquisite furniture for which he was renowned. Some years ago I took an American friend

by motor to see Dr Davies at the Manor House, and this year I met the friend again in New York, and he told me that the visit to that delightful house was one of the most vivid memories of his visit to England. Dr Davies was an Alpine climber for many years, usually making his headquarters at Pontresina, which he visited thus year. He was a great lover of the Alps, of cathedrals, and of all forms of grandeur and beauty. He had a special flair for old silver, Italian carvings, mezzotints, and old English furniture, in all of which he showed the most perfect taste. He had a fine appreciation of good food, wine, and cigars, and was a delightful host and companion. All who knew him will miss him greatly, and will condole with his widow and children, one of whom is a distinguished member of our profession.

Dr GEORGE MARTIN FOX, a practitioner very well known in South Staffordshire, died at Walsall on Sunday, September 27th. He was taken ill while in London, representing his Division at the opening of the new House of the British Medical Association in July, and died a couple of months after his return to Walsall. Born in Bilston, the son of the late Mr Charles James Fox, he took the L.S.A. in 1886 and the M.R.C.S. and L.R.C.P. diplomas in 1887, and, after a short period of practice in Willenhall, settled in Walsall some thirty-two years ago. Subsequently, he obtained the D.P.H.E.D. in 1897 and the M.B. D.U.I. in 1905. For many years he had been medical officer to the Walsall Workhouse and medical officer of health to the Walsall Rural District Council, as well as honorary physician to the Walsall General Hospital. He was a keen member of the British Medical Association, and for several years was Representative of the Walsall and Lichfield Division. There were few things he enjoyed more than a large and argumentative gathering of Representatives, particularly when followed by such an Annual Meeting as that at Glasgow or Portsmouth. He was especially interested in midwifery, and for several years he was the recognized teacher of midwives in Walsall. The constant night calls which this entailed seemed to worry him not at all, indeed, right up to his fatal illness his capacity for work was phenomenal. Dr Fox leaves a widow and one son, an officer in the South Staffordshire Regiment, now in India. His eldest son was killed in the war.

The death of Dr ROBERT REID RAYBOLD of Liverpool has removed one who, in former years, was a prominent figure in medical politics. He was educated at Edinburgh, Dublin, Belfast, and London, and took the diplomas of L.R.C.P. and S.D.M. in 1877 and that of M.R.C.S. Eng. in 1879, he graduated M.D.R.U.I. in 1880. He settled in general practice in Liverpool, from an early date he took an interest in the British Medical Association, and was at one time a member of the Parliamentary Bills Committee. He belonged to a group of active members whose chief opportunity of airing any grievance in the days before the formation of Divisions and the establishment of the Representative Body was either to give notice of motion at the Annual Meeting or move a resolution upon the Council's report then presented. For years no Annual Meeting agenda paper was complete without his voluminous notices of motions. He regularly attended the Annual Meetings and also the special meetings in Fether Hall held from time to time to consider the many contentious medico-political subjects under the old constitution. A fluent speaker and trenchant critic, scarcely anything the Association undertook escaped his caustic comment. He was elected one of the direct representatives for England on the General Medical Council but only served for eight months—from January 1st till September 1st, 1897—when he resigned.

We regret to record the death of Dr ANDREW JOHN GIBSON, at the age of 53, at Creetown, Dumfriesshire, to which he was paying a short visit. Dr Gibson was a native of the Hebrides and received his medical education at Edinburgh where he graduated M.B. C.M. in 1894. He served with distinction in the Boer war, and

was senior medical officer to the refugee camp at Uitenhage, Cape Colony. During the late war he served with the Canadian Medical Forces. In recent years Dr Gibson gave great assistance to the British Medical Association, of which he was a member, in connexion with the question of the prospects of British medical settlers in Canada. He was for some time a member of the Immigration Service of Canada, and for many years had been engaged in medical practice at Victoria, British Columbia. He recently removed to Duluth, Minnesota. A military funeral was given him at Creetown, all the local ex-service men attending.

Dr THOMAS ANDERSON ALEXANDER, who died on August 12th at his residence in Lpsom, in his 67th year, received his medical education at Edinburgh and in Berlin and Vienna. He graduated M.B., C.M. Edin in 1880, and M.D. in 1884. He had practised in the Lpsom district for forty-one years, and was medical officer to the Lpsom Urban Fever Hospital and honorary surgeon to the Lpsom and Ewell Cottage Hospital. After his retirement from active practice some six years ago he became honorary secretary of the Cottage Hospital, in which he took a keen interest. During the war he was largely instrumental in starting the Lpsom Ground and Stand Hospital for Wounded Soldiers. He was one of the original members of the Lpsom Golf Club, and in his early days was a member of the Lpsom Cricket Club. He devoted many of his holidays to fishing in Scotland, and was a member of the Epsom Angling Society. Dr Alexander was a member of the British Medical Association for thirty-six years.

The Services

HONORARY APPOINTMENTS TO THE KING

It is announced that Air Vice-Marshal David Munro, C.B., C.I.E., Director of Medical Services R.A.F. and Group Captain Hardy Vesey Wells, C.B.E., have been appointed honorary surgeon and honorary physician respectively to His Majesty the King.

DEATHS IN THE SERVICES

Colonel Robert Robertson Madras Medical Service (ret.) died on June 5th aged 60. He was born on December 10th 1864 the son of James Robertson of Dundee and was educated at Glasgow, where he graduated as M.B. and C.M. in 1886. Entering the Indian Medical Service as Surgeon on March 31st 1887, he attained the rank of colonel on June 30th 1913 and retired on June 30th 1918. He served in the Burmese campaigns in 1888-89 receiving the frontier medal with a clasp and also in the great war.

Brigade Surgeon Wellington Gray Bombay Medical Service (ret.) died on July 15th aged 85. He was born on September 29th 1841 the son of the late St George Gray of Drumranish. He was educated at Trinity's College Dublin where he took the Licence in Medicine in 1865 and that in Surgery in 1866. Entering the Indian Medical Service as assistant surgeon on March 31st 1866 he became brigade surgeon on September 1st 1883 and retired on April 12th 1893. He was the author of *The Botany of the Bombay Presidency in the Bombay Gazetteer*, published in 1886.

Universities and Colleges.

UNIVERSITY OF LONDON

UNIVERSITY COLLEGE

A public lecture delivered in English and illustrated with lantern slides on the photochemistry of vision will be given by Professor Fritz Weigert of the University of Leipzig on Wednesday October 7th at 5.30 p.m. in the Physiology Theatre. The chair will be taken by Sir John Herbert Parsons F.R.S. F.R.S.

A course of eight lectures on the physiology of hearing and vision will be given by Mr R. J. Lythgoe M.A. B.Cb. (Scholarship in Physiology) on Mondays and Wednesdays at 5 p.m. beginning October 12th. The lectures are open to students of the University and others interested in the subject without fee or ticket.

ST THOMAS'S HOSPITAL MEDICAL SCHOOL

The following scholarships have been awarded

Entrance Arts Scholarships (value £50) Mr A. G. Sanders and Mr J. F. E. Bloss
Entrance Science Scholarships (value £150) Mr H. M. Robertson (value £50) Mr D. O. Clark
The William Tate Scholarship (value £25) Mr A. M. Eas on

GUYS HOSPITAL MEDICAL SCHOOL

The following Senior Science scholarships have been awarded

O. A. Beadle (War Memorial Scholarship £20) L. T. Ride £20

Medical News.

H R H THE DUKE OF YORK, K G, will lay the foundation stone of the College House Extension at St Thomas's Hospital at noon on Monday, November 2nd. The ground and first floors of this building, which is being erected opposite the hospital in Lambeth Palace Road, will house the Students Club premises, while the upper four floors will provide resident accommodation for some sixty students, in addition to members of the resident staff of the hospital.

THE annual service of the Guild of St Luke will be held on St Luke's Day, Sunday, October 18th, in Westminster Abbey, at 6.30 p.m., when the preacher will be the Rev. Father Jenks. Those members of the profession desiring to take part in the procession are requested to wear academic dress, and to communicate beforehand with the secretary of the Guild, the Rev. H. Kirkland Whitaker, M.D., Chaplain's House, Banstead Downs, Sutton, Surrey.

THE first social evening of the new session of the Royal Society of Medicine will be held, as already announced, on Tuesday, October 27th, at 8.30. Fellows and then guests will be received by the President, Sir St. Clair Thomson, who at 9.30 will give a short address on 'Shakespeare as a guide in the art and practice of medicine'. The library will be open and various objects of interest will be exhibited, including a display of drugs mentioned in Shakespeare's plays, lent by the Wellcome Historical Medical Museum, and arranged by Mr. C. J. S. Thompson. The annual dinner of Fellows and Members of Sections of the Society will be held on Thursday, November 19th, at 8 p.m., at the Hotel Victoria, Northumberland Avenue. Tickets, price 15s. each, exclusive of wine, may be obtained from the Secretary, 1, Wimpole Street, W.1. Ladies may be invited.

THE Fellowship of Medicine will hold a series of free lectures on tuberculosis in the lecture room of the Medical Society, 11, Chandos Street, during October, November, and December. The first will be given on October 12th at 5.30 p.m., by Dr. L. S. Burrell, on tuberculosis from the physician's viewpoint. On Monday, October 5th, the Central London Throat, Nose and Ear Hospital will begin a three weeks' course in laryngology, rhinology, and otology. The operative surgery and the clinical classes may be taken together or singly. The London School of Hygiene and Tropical Medicine will hold the first two of a series of eight clinical demonstrations on October 6th and 8th at 2 p.m. Dr. G. C. Low and Dr. Manson Blair will consider the more important diseases of tropical countries. Other courses in October will be given as follows: a combined course in children's diseases at the Paddington Green Hospital, Victoria Hospital for Children, and Children's Clinic from October 12th, a course in urology at St. Peter's Hospital on October 19th, and a course in dermatology at St. John's Hospital from October 26th. Copies of any syllabus, together with the Fellowship programme, may be obtained from the Secretary, 1, Wimpole Street, W.1.

AT the meeting of the Royal Anthropological Institute to be held on Tuesday, October 6th, at 8.15 p.m., at 52 Upper Bedford Place, W.C.1, a communication illustrated with lantern slides and exhibits on early man in Palestine and the Galilee will be made by Mr. F. T. T. Petro and Sir Arthur Keith. At the meeting held on Tuesday of this week Dr. Aleks. Hrdlicka (Washington) exhibited the human skeleton remains recently discovered by him in the Rhodesian Man Cave, Broken Hill, Rhodesia, and discussed the nature of the deposits of the cave.

A POST GRADUATE course will be held at St. Mary's Hospital during this week end (from October 3rd to 5th inclusive), open to all medical practitioners without fee. The subjects to be dealt with include the management of urinary obstruction, differential diagnosis of gall stones, haemorrhagic ovarian cysts, minor surgery and some applications of physiology in general practice, clinical aspects of malignant disease of the colon, overlooked causes of fever in children, clinical types in gynaecology, chronic toxæmia, and cancer of the breast. The first class commences at 11 a.m. on Saturday; two classes will be held on Sunday morning, and the Monday classes extend from 10 a.m. to 4.45 p.m.

A COR in the children's ward of the Bristol General Hospital was on September 25th, dedicated to the memory of the late Dr. Alexander Cochran.

MR. C. C. CLAYTON, C.B.E., Ph.D., M.P., a director of the United Alkali Company, and Professor H. C. H. Carpenter, F.R.S., Professor of Metallurgy in the Royal School of Mines, have been appointed to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

THE freedom of the Royal Burgh of Tain was conferred upon Mr. John Fraser, professor of clinical surgery in the University of Edinburgh, on September 25th. In an address the Provost recalled the fact that Professor Fraser was born and educated at Tain, and that after his graduation at Edinburgh he specialized in surgery, he had gone from strength to strength and from honour to honour until his name was known throughout the land as one of the most skilful and successful surgeons of the day. The Right Hon. Ian Macpherson, M.P., and Sheriff Principal Mackintosh congratulated the youngest burgess upon the honour conferred upon him. A public luncheon was subsequently held at the town hall, when the health of Professor Fraser was pledged with enthusiasm.

THE memorial cross erected by the Imperial War Graves Commission in the naval war cemetery at Lyness, Orkney, was unveiled on September 29th by Sir William Watson Cheyne, Bt, F.R.C.S., F.R.S., Lord Lieutenant of Orkney and Shetland. The ceremony was attended by representatives of H.M.S. *Nevenge*, the flagship of the Atlantic Fleet, and of H.M.S. *Uchagay*. Sir Watson Cheyne, it will be remembered, served as consulting surgeon to the Royal Navy with the rank of Surgeon Rear Admiral during the great war.

MR. BASIL GRAVES, who was recently appointed honorary surgeon to St. Paul's Eye Hospital, Liverpool, has been given temporary leave in order to conduct a post graduate course at the Bellvue Hospital Department of Ophthalmology, New York University, on the advanced principles of special methods and technique employed in clinical microscopy of the living eye.

THE first annual Norman Lockyer lecture, established by the British Science Guild as a means of periodically directing the attention of the public to the influence of science upon human progress, will be given by Sir Oliver Lodge, F.R.S., on Monday, November 16th, at 4 p.m., in the hall of the Goldsmiths Company (by kind permission of the Master and Court of Assistants of the Company). The subject of the lecture is 'The link between matter and matter'. Tickets of admission may be had from the Secretary, British Science Guild, 6, John Street, Adelphi, W.C.2.

THE third session of the Liverpool Psychological Society will open on October 6th, when Mr. G. C. Field M.A. will deliver the President's inaugural address at the University. In the society's syllabus prominence is given to the psycho-analytic and medical aspects of the subject. The programme may be obtained from the Secretary, the University, Liverpool.

THE annual business meeting and autumn dinner of the Queen's University (Belfast) Club London will be held at 7 and 8 p.m. respectively, on Thursday, October 15th, at the Connaught Rooms, W.C.2. Members of the University wishing to join the club are invited to communicate with the Honorary Secretaries, 132, Harley Street, W.

THE autumn general meeting of the Institution of Heating and Ventilating Engineers will be held on October 6th, at Caxton Hall, Westminster, at 7 p.m. A paper by Mr. E. Over, B.Sc., on the practical measurement of air flow, will be followed by a discussion.

SEVERAL courses of lectures have been arranged by the British Institute of Philosophical Studies for the coming session, which opens on October 5th. Professor I. H. Pear will lecture on psychology, Professor James Johnstone on life and man, and Professor Leonard Russell on the conception of matter. An announcement of these lectures will be found in our advertisement pages.

THE British Social Hygiene Council will hold a dinner on Monday next, October 5th, at 8 o'clock, in the Prince's Restaurant, Piccadilly, to meet the members of the second Imperial Social Hygiene Congress.

THE fortieth annual meeting of the Caledonian Medical Society will be held at the Central Station Hotel, Glasgow, on Friday, October 9th, at 3 p.m., under the presidency of Dr. Neil F. Kerr. This is the third occasion on which the society has met in Glasgow, since the last meeting in 1914 the membership has increased from 275 to 420. Any member of the medical profession will be heartily welcome to attend, and members may introduce lay friends. Dr. Kerr kindly invites the members to tea after the meeting. The annual dinner will take place the same evening, at 7.15 in the Central Station Hotel, tickets, exclusive of wines, 12s. 6d. each.

THE Council of the Harveian Society of London has selected the following subject for the Buckton Browne prize: 'The etiology of high blood pressure and of the respiratory phenomena associated with high blood pressure and chronic nephritis'. Particulars regarding the prize will be found in our advertisement pages this week.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **British Medical Journal** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **British Medical Journal** must communicate with the Financial Secretary and Business Manager, British Medical Association House Tavistock Square W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

QUERIES AND ANSWERS

VACCINES FOR SLEBORRHIC ALOPECIA

"M" inquires whether acne vaccine or autogenous vaccines have ever been used for premature baldness (alopecia simplex) due to sebaceous disease and with what results. The patient is a male 30 years of age and our correspondent would be glad of hints for treatment.

INCOME TAX

Partnership Practice—Assessment

"R C W" has lately taken a partner and has been informed (1) that a partnership is assessed in one sum to income tax and (2) that the books are required to be audited by a recognized accountant.

"* (1) This is correct according to law and practice the amount of tax payable, however is not affected, as the partnership assessment is merely the aggregate of what would be the several liabilities of the separate partners. "R C W" should remember that the assessment should be based on the past three years' profits of the practice not including for instance the earnings of his new partner before joining the partnership. (2) We know of no such obligation attaching to partnerships as such. It may however be true that partners frequently adopt the rule of employing an independent accountant to certify the amount of profit divisible between them and that where that is done the revenue authorities expect, perhaps not unnaturally, to have the income tax returns corroborated by production of copies of the accounts.

Book Debts—Sale of Practice

"G L C" gave up his practice at April 30th 1925. The inspector proposes that he shall account for tax (1) on one twelfth of the (average) income tax assessment for 1925-26 plus (2) on the amount of the book debts due to him on April 30th 1925.

"* (1) Is correct, (2) is incorrect. It is not a fact that this amount of book debts has not been taxed. G L C has paid tax year by year on his earnings for this financial year. It is true that an artificial basis was adopted for computing the amount of those profits—for example the three years' average of his cash profits but that (cash) basis was adopted for mutual convenience as being in the long run equivalent to the value of book debts and expenses incurred" basis. The proposition that the amount of these debts is not chargeable to income tax is the corollary of the revenue's proposition that the cash basis is not permissible in the early years of a practice.

Motor Car Transaction

J C O R states that the inspector refuses to allow the excess of the cost of a new Rover car over the amount received for a side-car combination.

"In so far as the cost represented outlay on improving the equipment of the practice it is undoubtedly capital expenditure and as such inadmissible. What J C O R is entitled to claim is the difference between the cost to him of his side car combination and the amount he received for it."

Enlargement of Garage

"J B W" explains that, in consequence of purchasing a larger car he has had to expend money on enlarging his garage and entrance gate. Is there any allowance for this?

"* No, the expenditure relates to an improvement and as such must rank as capital expenditure. The renewal cost of the old car is, as "J B W" suggests the excess of its cost to him over the amount received for it but the depreciation allowance is due on the full cost (£300) of the new car."

LETTERS NOTES ETC

A DISCLAIMER

Drs D JUSTIN DAVIES and LUCY S DAVIES (Leicester) write: Will you allow us through the columns of the **JOURNAL** to disclaim all responsibility for paragraphs which have appeared in the public local press concerning us? Not only have such references been unsought by us, but have caused us great distress and have in every way been actively opposed by us.

THROUGH EXPRESS TO THE RIVIERA

THE through express Calais-Vintimille (in connexion with the 11 o'clock service from Victoria) will be reintroduced as from November 2nd. This train will provide sleeping accommodation in the form of wagon lits lits salon, and couchettes also first and second class ordinary seats and restaurant car. Accommodation may be reserved at the P L M Railway Offices 179, Piccadilly, W 1, or through any touring agency.

MEDICAL WOMEN IN THE SEVENTEENTH CENTURY

DR C SUFFEAD (London N) sends the following extract from the *Genealogist's Magazine* relating to the licensing of two medical women to practise in the reign of James I.

"... in the month of November 1613 granted a licence to Anne ..."

as those granted to men

ences are contained in the same

Syringe for SELF ADMINISTRATION OF INSULIN

DR T MABURY HILLIARD (Blackpool) writes to recommend a modification of the Record syringe which he has devised in order to ensure automatic control of the dose of insulin thus enabling the patient to administer it himself. By means of two lock nuts on the piston shaft any required dosage may be obtained without risk of alteration or the destruction of material by frequent sterilization. The syringe is made by Messrs Allen and Hanburys.

THE ROAD TO OLYMPIA

We are asked to say that medical practitioners who are members of the Automobile Association and intend going by road to the Olympia motor show may obtain full directions as to the best routes from the patrols at the A A telephone boxes on the outskirts of London.

COLOUR SCREENS

DR HORATIO MATTHEWS (London W) sends the following note for the information of those medical men who take a practical interest in the technique of colour photography. He writes: In colour photography the registration of this fine colour screens is a matter of some difficulty. It was thought, however that the cinema film which allows the use of much coarser colour screens, should be used. The screen is so simple as it looks, but is operated by delicate machinery. The threads must have been costly pastimes. The method I adopt is simple and inexpensive. Since it breaks down however where every other attempt must finally do—namely at registration of one film with another for purpose. I have no further use for it, and willingly give it to any other worker in this field. My method is to grease mats then to cut the surface by compound knives and then to pass the film on to the dry bath. This stains the exposed part of the film along the fine cuts made by the knives but leaves the greased part protected and ready for further operation by the knives and different colouring.

VACANCIES

NOTIFICATIONS of offices vacant in universities medical colleges, and of vacant resident and other appointments in hospitals will be found at pages 43 44 45 48 and 49 of our advertisement columns and advertisements as to partnerships assistantships and locum tenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at pages 119 and 120.

British Medical Association.

PROCEEDINGS OF SECTIONS AT THE ANNUAL
MEETING, BATH, 1925

SECTION OF THERAPEUTICS

Professor R B WILD, M.D., F.R.C.P., President

DISCUSSION ON
TREATMENT OF CHRONIC ARTHRITIS

OPENING PAPERS

I—Sir THOMAS HORDER, Bt, K.C.V.O., M.D., F.R.C.P.

[Abstract]

THE key to success in the treatment of cases of arthritis is given by a full consideration of the etiological factors entering into them.

These etiological factors are various, and in the great majority of cases, if not in all, more than one factor is present. In many cases several factors contribute to produce the clinical picture. In such cases the more correctly the value of the particular factors is estimated and dealt with the better will be the response to treatment.

No doubt in some cases there are etiological factors which are at present obscure, this applies especially to the group of arthritides to whom the term "rheumatoid" is given. Here the value to be assigned to the factor of microbial infection is often doubtful.

But that the *infective factor* is present to some extent in almost all cases of chronic arthritis seems certain, though the degree, and the manner of its operation, are not seldom difficult of elucidation. Even in cases which at first sight seem independent of infection there are good reasons for thinking that the microbial factor is contributory. Joint disease due primarily to trauma, to gout, and to trophic diseases of the spinal cord are instances of this statement.

If we construct a table of the various types of arthritis met with recording as the element of infection is a dominant etiological factor, or recording as it is not, we should get some such result as this:

INFECTIVE FACTOR	Joint Disease	
	High	Low
	<ul style="list-style-type: none"> Conorrhoeal rheumatism Chronic pyaemia Arthritis due to streptococcal, pneumococcal, dysenteric, and coliform infections Tuberculous and syphilitic arthritis 	<ul style="list-style-type: none"> Arthritis in association with focal sepsis Rheumatoid arthritis Osteoarthritis
	Gout	
		<ul style="list-style-type: none"> Arthritis in tabes syphilis, omphelia, hemiplegia and paralysis agitans
		Trauma

The brackets indicate roughly certain groups of cases having close resemblances when regarded from the etiological point of view.

Arthritis as a definite expression of *focal sepsis* forms an intermediate group between the cases of direct joint infection and those termed "rheumatoid," which, owing to our present ignorance of the degree to which the element of infection is present, form the crux of the therapeutic problem.

Drainage

In this intermediate group, drainage or other appropriate treatment of the area of focal infection is the first step in treatment. But it is essential to explore the whole field before condemning any one area unless the evidence against this area is overwhelming. More than one area is sometimes involved, in which case it is important to

determine as far as possible which is primary, and attend to that first. If teeth and tonsils, or teeth and gastrointestinal tract, are both involved, the teeth should receive thorough attention and an interval be allowed before drastic measures are employed in regard to the tonsils and the bowel. So also with the throat or nose on the one hand and the rest of the respiratory tract on the other.

Although it should probably be an invariable rule to disallow all "devitalized" or dead teeth in arthritides, it is advisable to explain the reason for this fully to the patient, and to get him to accept joint responsibility for the sacrifice of mechanically useful teeth. Apical infection can, of course, only be determined or excluded by a good set of radiograms.

Both the prostate and the uterus are capable of holding up micro-organisms and causing chronic arthritis without evidence being available from even the most thorough bacteriological examination. In the absence of evidence of focal sepsis elsewhere, the history of prostatitis at some previous date justifies treatment based upon this origin being the seat of infection. Previous emetage, for whatever purpose undertaken, similarly lends presumptive evidence, though less strong, to regarding the uterus as the seat of focal sepsis.

In the alimentary tract, although the caecum, appendix, gall bladder, diverticuli are occasionally the source of the toxæmia, the area infected is much more often diffuse, and probably the greater part of the colonic mucosa. It is here that the bacteriological evidence is least decisive in regard to diagnosis. Not every arthritis whose stools are reported to contain atypical organisms owes his disease to this fact. On the other hand, it is quite common to receive a bacteriological report that the intestinal flora are normal in cases in which the arthritis is an expression of intestinal subinfection. It is regrettable that there is not more uniformity amongst laboratory workers in regard both to nomenclature and to technique in these investigations.

Streptococci, both hæmolytic and non hæmolytic, are probably by far the most common micro-organisms concerned in the infective element in arthritis. This holds good equally for intestinal as for other subinfections. Advantage may be taken of this fact in treatment when the bacteriological evidence is indecisive.

Antigen therapy should be supplementary to drainage of the infected area, not a substitute for it. The decision to employ antigens should be deliberate, and the decision being made, the choice of remedy and system of dosage should be very carefully considered. The patient should be warned against quick results and encouraged to co-operate in a thorough trial. His immunity mechanism should not be flogged, but rather coaxed, by the remedy.

In undertaking drainage of the intestine, consider the diet, both from the point of view of lowering the bacterial content and from that of mechanical cleansing. These considerations are probably of greater importance than is the use of "intestinal antiseptics." Amongst the latter measures, however, the older agents, such as mercury and salol, should not be forgotten. The value of a drug is rarely proportionate directly to the amount of money spent upon advertising it.

Chronic Arthritis Part of a General Disease

In the great majority of cases chronic arthritis is part of a general disease. The patient requires treatment as much as, and sometimes more than, the joints. This fact involves two important factors—the nutritional and the nervous, they overlap in many cases.

Nutrition and Nerves

In treating the *nutritional factor* the general habits must be passed in review. Much the same regime should be adopted as is followed in any case of chronic infection—for example as in pulmonary tuberculosis is ample fresh air, bodily and mental relaxation, the avoidance of colds, a full and liberal dietary and graduated exercise. Diet fads are to be rigidly avoided. The best drugs in this connexion are vitamin, iron, cod liver oil, and the hypophosphites.

On the *nervous plane* a series of strains should be remembered: emotional shock, the prolonged nursing of friends or relatives, child-bearing, the menopause, fears of crippling, etc. The more robust forms of psychotherapy are often indicated. Habits of invalidism and the paraphernalia of the sick-room must be combated.

As part of the general disease, *endocrine disturbances* are not seldom present, giving the endocrinologist a large field to exploit. Small doses of thyroid are often helpful, especially in the older patients.

The *metabolic factor* is difficult to assess, but should be carefully sought. The experienced observer can often detect the factors of gout even in the presence of obvious sepsis. To omit appropriate treatment is to leave untouched an important and sometimes very amenable part of the pathogenesis. Colemium and alkalis are indicated for acute or subacute exacerbations, in chronic conditions atophan or atequinol should be tried. The last named drug is sometimes very useful even when gout is not obviously present.

For effusions, whether into the synovial membranes or into the articular and periarticular structures, iodine is invaluable, and should be exhibited with system. Better than the potassium salt probably are certain organic derivatives, but nothing seems to excel the tincture, given in the form of the French Codex preparation (10 per cent). It is best ordered in minimum doses, taken in milk, between meals. 1 minim a day with an increment of 1 minim daily until 30 minims are reached, keeping at this dose for a month, and then gradually diminishing, the course being thus one of three months' duration. When the dose reaches 6 minims daily it may be taken in two doses, and when the dose reaches 9 minims it may be taken in three doses.

The best treatment for the state of *physical and mental depression—misère*—so common in arthritis, is on the lines already mentioned under nutritional and nerve factors. For the relief of pain in addition to the local measures (see below) there is nothing as a rule so helpful as aspirin. This drug is perhaps disallowed too frequently, or only permitted parsimoniously. But it is doubtful if the disadvantages are so great as is often thought. Its greatest disadvantage probably is that it often renders patients less inclined to co-operate with the more fundamental points in their treatment owing to the comfort they get from its use. But it is doubtful if there is greater value in denying them this comfort. The best time to give aspirin is at bedtime. Pyrimidon is also useful for pain. If narcotics are used, and this should only be in exceptional cases, small doses of codein may be chosen, combined with aspirin and caffeine. Blisters and counter-irritants have their uses.

Climato is perhaps of less moment or is certainly less popular in treatment to-day, with increased knowledge of the various factors at work, than formerly. The indifferent food, the risk of intercurrent infections, and the strain of travelling make a trip to foreign climes of dubious advantage. There is the added obstacle that such an enterprise holds up most of the other helpful measures of treatment.

Considerations of *spa treatment* I will leave to those who follow me and who are expert in its principles and applications. It is sometimes said that the modern conception of the infectivity of most cases of chronic arthritis makes the idea of spa treatment irrational. But taking the view that arthritis is a general as well as a local disease, this reasoning becomes fallacious. If, as already observed, the metabolic, the nutritional, and the nervous factors enter into many cases, it is clear that there is a large function for spa treatments, quite apart from the local effects upon the joints. Spa practitioners are twitted, somewhat pardonably in that they have added the Plombières douche, the extraction of dead teeth, and even the exploitation of vaccines to their former armamentarium, thus exposing the slender nature of their indigenous weapons. But, quite apart from the fact that patients will often take even these things much more seriously at Bath than at Brixton, there is undoubtedly a great field for the treatment of the chronic arthritis by spa measures as ever. Of radium waters and radio-active mud we are only now beginning to learn the potentialities, nor shall we probably get further

until we have some reliable means of assaying the content of the active principles.

Local Treatment

In dealing with the local treatment it is necessary to remember that structures other than the mere tissues of the joint proper show the effects of inflammation and malnutrition: the bursae, the tendon sheaths, the fasciae, the nerve trunks, the skin, and especially the muscles. If local measures are to be really useful, all these must be passed in review and their condition noted. No mere rule of thumb treatment is of any service, rather does such absence of method or reason often render disservice. *Massage*, so eminently useful in the majority of cases, is grossly abused in others, where muscle spasm exists as a contraindication, though usually temporary. *Ionization* and *diathermy* have their advocates, and what is termed, with an attractive note of hope and economy, electrical massage. Unless the electrotherapist can tell us clearly what is his conception of the pathology of the local condition and what it is he aims at doing, we may at least hesitate to follow his advice, however enthusiastically given. There is one *sine qua non* in regard to all local measures, and that is the necessity for getting the patient's confidence, unless this is secured the result is doomed to failure.

In the restoration to function of the wasted muscles and the stiffened joint, active movements undertaken by the patient take a very prominent place. No amount of merely passive movement ever succeeds in substitution for this. Therefore the patient must be constantly encouraged, adjuved, if necessary almost, though never quite, threatened into making these efforts for herself under pain of permanent crippling. Simple forms of apparatus which assist voluntary efforts are useful—balls of different sizes to be clenched by the hands, the wheel of a sewing machine for the wrists and shoulders, a treadle machine for the ankle and hip.

General Effects of Local Treatment

All efforts made to restore and improve the function of diseased joints react beneficially on the disease itself. This should be explained to the patient. Moreover, the practitioner should have constantly before him the possibility of spontaneous arrest of the disease, or arrest as the result of his general treatment. For the patient to arrive at this desideratum with joints irrevocably fixed, or with joints still partially mobile, is so great a difference as to justify every effort, since from now onwards much more approximation to normal function than might be expected may well follow persevering with methods of re-education.

The orthopaedic treatment of fixed joints resulting from chronic arthritis is a science and practice in itself. Its importance is even yet scarcely appreciated. The first essential to correct methods is a good radiogram. The second is examination under a general anaesthetic. Experience shows that in many cases several slight forcible movements, at intervals determined by the particular case, are better than one severe wrench.

II—PRESTON KING, M.D.,

Honorary Consulting Physician Royal Mineral Water Hospital, Bath

I FEEL it a great honour to be asked to bring before you the hydrotherapeutic treatment of these arthritic cases of which Sir Thomas Horder has spoken. And first may I say with what pleasure I have listened to Sir Thomas's very able and interesting address upon the subject.

In discussing the treatment of chronic arthritis, and especially when doing so in this city, our thoughts must necessarily turn to the thermal water, for these cases form the majority of all those that come to Bath for help. I have no fear in bringing this form of treatment to your notice, for after many years of experience I am fully convinced of its efficacy.

I think that this branch of therapeutics is not properly understood or sufficiently appreciated by a great number of the members of our profession. By some, spa treatment, if it is not still looked upon as a mild form of delusion, is

regarded as something which will do no harm, and may at least be tried. I hope, in what I have to say to show you that it is far more than this, that it is, indeed, of real benefit in chronic arthritis, and supplies a way to relief that is wanting by all other means. As Sir Thomas Horder says, we are sometimes tempted for adding Plombières, massage, electricity, etc., to our means of cure, as if we did not believe in the waters by themselves, but I would like to remind you, gentlemen, that the thermal waters, in their internal and external use, are to be regarded by their reasonable advocates as one of the constituents of our pharmacopoeia, and, like any other of these remedies, they have their proper use in appropriate cases, and in none more than these we are considering. I want what I have to say upon the subject to do to be understood as applying to spa treatment generally, and anywhere but naturally my remarks must be chiefly based on what is done here, since I have no experience of water treatment anywhere else.

Bath possesses the only thermal springs in the United Kingdom. The waters rise to the surface at a temperature of 117°F and in a volume of about half a million gallons daily. The analysis of these waters is open to you all, and is contained in the handbooks that are published so I need not trouble you with that now, beyond saying that they contain no specially active salts, and are therefore classed among those that are called "indifferent." These various "indifferent" spa waters, however, are all known to have a special character of their own in the treatment of disease, but to what that special character is due we do not know. Bath waters are slightly diuretic as compared with ordinary water, and are also iridiorretic to a marked degree. Naturally this latter fact is made much of by the city authorities in matters of advertisement, but whether we are justified in laying any stress on this property to explain their action I do not know. I do know this, however, and it is one thing that is certain about their use—and that is that certain cases, and especially those which are due to gout, do improve here in a wonderful way.

There is one other factor which helps in water treatment, as in all other medicines we prescribe, which is beyond the reach of the analytical chemist, and that is faith, which works towards recovery. The patient, after a long illness and the use of many remedies, finds himself at a health resort, amid surroundings laid out for treatment, and in a place where the whole atmosphere breathes hope of recovery. Faith and suggestion of good to follow help him. But, indeed, the waters and the "cure" generally are not peculiar in this matter. Faith and suggestion of help are in all the medicines we prescribe if they are to aid recovery, and this power of suggestion will often vary with the hand that writes the prescription. I entirely agree with Sir Thomas Horder that it is necessary to gain the patient's confidence. For instance, some quite simple mixture given by a great Harley Street physician will contain this force to a high degree, it will be treasured for years and handed round to friends with never-failing good effect. The modern psychoanalyst has done his best to ride this useful steed, suggestion, to its death, he would almost have us believe it was now forled in his own stable, forgetful of the fact that its first sire was coeval with the art of medicine.

Chronic arthritis must be taken to include all those joint affections which vary from the early synovial swellings to the advanced cases of osteoarthritis. It is the result of many different causes and cannot be classed as a distinct disease. Even the milder and the more severe forms of which I have spoken have by no means any necessary connexion with each other for the origin and cause of each is often quite distinct. Modern pathology has shown that the arthritis often results from an infection in some distant centre very frequently from the teeth. When a pathogenic organism is found a vaccine is made, and used in many cases with very encouraging results. Often no such organism can be isolated, and then we are driven back to some irregular attack of gout or rheumatism or to an old and half forgotten injury for the cause. Sometimes even this fails, and the attack seems to have "come of itself." From all this it will be understood that in treating

chronic arthritis by hydrotherapeutic methods we are treating results, and not causes, and the cases as we see them will vary, as I have said, from those of slight stiffness and pain on movement and a little synovial thickening to those later stages of disorganized joints with eroded cartilage, irregular bone formation, and fibrous or even bony ankylosis. These patients come for cure, but it is obvious that no benefit, beyond perhaps some alleviation of pain, is possible.

In the treatment of chronic arthritis by waters, or by any other means, it is not only the stiff and painful joints, but also the patient behind them that we have to think of. It is of little use in the end to see the swellings reduced and the joints more free if the general health suffers in the process. This especially applies to those asthenic cases of rheumatoid arthritis in women where the fusiform synovial enlargement of the joints, especially of the smaller ones, is accompanied by a quick pulse, a moist skin, and general debility. Such cases not only do not improve but tend actually to get worse by bathing. For them a general tonic treatment, with good food, fresh air, and massage, is by far the best. Some casts of hands from cases such as these are shown. I took them many years ago at the Mineral Water Hospital.

In treating chronic arthritis by means of baths it can easily be understood how grateful to the patient is the immediate effect of the hot water, it lessens the tension and relieves the pain and allows more movement to the joint. Bath, with its abundance of hot water, can supply this treatment freely in its so-called deep and reclining baths. This is its oldest form of cure, the one upon which its reputation was first founded, and it still remains its peculiar specialty. Immersion in the water is followed by the patient in hot sheets and blankets for from fifteen to twenty minutes, and this time might be extended with benefit and comfort. A glass of the water is taken while in the bath, and this encourages a more healthy action of the skin during the pack.

Another very useful method of using the waters in these cases is by means of the Air and Vichy douche and massage system, and I would here enter a mild protest against the continued use of these foreign names, if I use them to-day it is because we have no generally accepted English terms to take their place. In these treatments the patient is not immersed in a bath but has streams of water directed on him while seated on a chair, as in the Air system, or when lying on a padded table, as in the Vichy. The latter has thus the advantage in certain cases of allowing a more complete relaxation of the muscles, while the massage is taking place in either case attention is especially directed to the joint affected and the treatments are followed, as in the case of the immersion baths, by rest in the hot pack.

In some cases of chronic arthritis the colon is suggested as being the source of the trouble and infection. Whether this is exactly so or not, the fact remains that much benefit follows a thorough washing out of this organ. This is done by means of the Plombières system, where a pint or more of hot water is allowed to flow into the rectum, acting as an ordinary enema, to be followed by another and more copious flow which reaches the whole course of the colon. It can easily be understood that a thorough irrigation of this kind does much good by washing out the larger bowel and removing certain accumulations of small deposits that are not got rid of naturally.

And then for the more direct treatment of affected joints by water there are the aerated and whirlpool baths. These came into use during the war for the treatment of injured limbs. As their name implies, the water is in a violent state of agitation as it flows in under considerable pressure and out again. During this treatment the limb is subject to severe pounding, and massage by the water with the result that pain and swelling are relieved and mobility assisted.

Many cases of chronic arthritis improve more when active movements on their own part are encouraged rather than when they are subject to the passive movements by the masseur. For these the warm swimming bath is very useful. In this supported by the water, with plenty of room to move the limbs can be freely exercised and extended and a coordination in walking is established. The tone of the

muscles is also restored—and, after all, there are no muscles so suitable for moving a joint towards recovery as are its own.

A properly equipped bathing establishment such as you see here, or at any other of our English spas, contains many subsidiary forms of treatment for chronic arthritis. Ionization is one of these, and can be applied directly to the joints affected through packs of lint soaked in a weak solution of sodium salicylate, lithium, or an iodide, it is often of great use in reducing the synovial swelling. Then also there is the radiant heat, either by the Greville or the Dowling system, where the whole body or a particular joint is exposed to a temperature considerably above boiling point. And then there is a room which looks like a cross between a gymnasium and a torture chamber, where by mechanical contrivances passive or active movements can be obtained by means of wheels and pulleys. This system is useful in some of these cases of chronic arthritis where the stiffness of a joint is due to fibrous adhesions. It can easily be understood, however, that it needs using with care, lest by too much force the condition of some quiet joint be converted into a more acute and painful arthritis.

These various treatments—electricity, heat, movements—the adjuncts of a bathing establishment, can, of course, be obtained at home, but, if they are used there at all, it is perhaps only in a half-hearted fashion. They are certainly of more help in conjunction with the waters and during a course of baths. In many cases of chronic arthritis when ionization, for instance, has previously failed, it is found to give relief during a course of treatment here.

In conclusion I would ask you not to judge only of water treatment in chronic arthritis by what I feel I have very imperfectly laid before you to-day, but to see the process and perhaps try it for yourselves, and on your return home I suggest that you try it for some of your gouty and rheumatic patients by sending them, not abroad, but to Bath, or to some other English spa, instead.

GENERAL DISCUSSION

Dr NATHAN MITCHELL (London) said that the generally accepted methods in the treatment of chronic arthritis were the eradication of the foci of chronic infection and the improvement of the circulation in the joints by electrical and other measures. The results were good, but there were some failures, and many of the "cures" were incomplete. If the general validity of the original hypothesis was accepted, and the potency of the therapeutic agents admitted, adequate explanation of the lack of universal success was needed. It could be furnished as follows: (1) Swallowed organisms frequently set up chronic infection of the bowel. Infective streptococci could be recovered from the stools of most patients with chronic arthritis, even many years after extraction of teeth. Cultures taken at laparotomy showed the widespread nature of streptococcal infection of bowel. Organisms were most abundant in the ileo-caecal region, but might extend upwards in pure culture as high as the duodenum, and could be recovered from neighbouring lymphatic glands. Staphylococcal infection of the ileum and lymphatic glands also occurred, but less commonly. (2) General depression due to toxæmia of ordinary intestinal putrefactive type might nullify all efforts to stimulate the body to throw off the chronic infection of the joints. (3) Endocrine defects (especially thyroid), often caused by the same subinfection as the lesions in the joints, handicapped the defensive mechanism seriously. (4) Secondary invasion of damaged joints by other organisms had also to be considered. Focal infections induced by autogenous vaccines suggested strongly that streptococcal infections sometimes followed upon a primary staphylococcal arthritis during the height of which staphylococci had been grown from the fluid in the joints, and that secondary invasions by intestinal streptococci sometimes affected joints originally damaged by streptococci from the mouth. He intended shortly to publish an account of cases of chronic arthritis due to *B. fallax*, a little known microbe studied in the past chiefly in connexion with war wounds. This organism could be grown from articular cartilage removed at opera-

tion. In certain insidious cases it had appeared to be the primary bacteriological factor, but it probably played an equally important part as secondary invader, keeping up residual inflammation in joints already damaged by infective cocci. In such cases a small overdose of the corresponding vaccine sometimes precipitated an attack closely resembling acute rheumatism of childhood, even in middle-aged patients suffering from arthritis of very indolent type. It formed agglutinins readily, and with correct dosage improvement was rapid and uniform.

Dr C. B. FRANK (Medical Officer in Charge Electro-Therapeutic Department, Royal Free Hospital) thought that in the very helpful survey of the etiology and treatment of chronic arthritis by the opening of the discussion three points stood out in particular: first, that chronic arthritis was not a local but a general disease, secondly, that some factor (or) was responsible for the determination of its various local manifestations, and thirdly, that success in treatment depended largely on the ability to break into the vicious circle of the very chronic or stationary type of cases. From every point of view, and especially that of the electrotherapist, he found himself in sympathy with the broad outlook taken by Sir Thomas Horder, and he therefore ventured to put forward some tentative views as regards the importance of certain physical types in determining the nature and course of chronic joint affections. In practice, even electrotherapeutic department there were always to be found very many cases of chronic arthritis undergoing various forms of electrical treatment. From amongst these cases could be picked out one group who, while making little or no progress to recovery, were tolerably comfortable as long as they could continue treatment, but who lost ground as soon as this treatment was discontinued. This group, for want of a better term, might be called the stationary group. Then there was a smaller group of patients who were making steady progress towards recovery, and this might be called the progressive group. Finally, there was an all too large group who derived no benefit from electrical treatment, and whose crippling slowly advanced year by year—the "permanently unfit for occupation" group. It was remarkable that in each of the groups receiving some benefit—namely, the stationary and progressive groups—they found a curious selectivity as regards treatment, one patient responding only to ultra-violet light, another to radiant heat, another to diathermy, another to citrophoresis, and others only to combinations of these treatments. A close study of the affected joints showed first of all that clinically similar joints were to be found in each of the three groups, and it was therefore not possible to prophesy merely on inspection of a joint how favourable or unfavourable response to electrical treatment would be. Nor was it possible to foretell, except in rare cases, from the condition of the joints alone the kind of electrical treatment likely to be beneficial. There existed apparently similar joints requiring different electrical methods, while clinically dissimilar joints might be benefited only by one kind of electrical treatment. It would therefore appear that some factor not connected with either the causative organism or toxin or with the situation of this organism determined the nature of the joint swellings, and whether these should be resistant or not to treatment. Long experience in the detailed examination of pilots and others had made him aware that in all probability there were certain basic physical types, and he was strongly of opinion that differences in these types largely determined the response of the joints to the infecting source and the ultimate reaction to treatment. In this connexion Draper's recent work on physical types in relation to disease was of particular interest. Primarily, the examination of any fresh case should therefore be directed to assessing the type of innate physical constitution, and secondarily to the site and extent of any focus. When special examinations for pilots were first instituted there came to be recognized a cardio-vascular debility type, a nervous instability type and a malnutritional type. Briefly, the cardio-vascular debility type presented a rapid pulse with a poor response to exercise, cold, clammy, and poorly coloured extremities, abnormal engorgement of the jugular veins,

a high pulse pressure, and allied signs. The nervous instability type presented exaggerated reflexes, tremors, poor sense of equilibrium, and generally erratic responses to any test to which they might be put. The malnutritional type were chiefly noticeable from their sallow complexions, poor posture, abnormal mobility of joints, and tonelessness, particularly of the antigravity muscles. If cases of chronic arthritis were regarded from this standpoint, it was easy to understand differences in the pain, joint swelling, or destruction of articular surfaces that might be found from case to case. Also, since the extent of any cardiovascular debility might roughly be measured, and since they knew by the researches of Group Captain Fleck that flying stress was proportional to the degree of pre-existing cardiovascular or other debility, they obtained perhaps an explanation of why apparently similarly affected joints responded in different degrees to treatment. His next step when examining any case of chronic arthritis was to determine the presence or absence of any of Head's areas of hyperaesthesia. This he carried out, not by Head's usual procedure, but by employing a small faradic current, and although this current would not define areas, as Head pointed out, as accurately as the pin method, he was of opinion that it did differentiate the degree of hyperaesthesia or hyperaesthesia accurately and rapidly. The presence of a positive zone should not be used to make a diagnosis of this or that focus of infection, but should be regarded merely as a strong and reliable indication that the corresponding organ was in a state of abnormality. The nature of this abnormality must be determined by other methods. But as long as any definite zone was present in a case of chronic arthritis, the rate of response to electrical treatment was certain to be unsatisfactory, and treatment directed to the organ indicated by this or that area had, in many cases, proved of benefit, particularly in prostatic and cervical cases. As a further guide to the selection of treatment he had formulated certain rough or tentative working rules, as follows: (1) That there was, not seldom, some definite clue to the causative disease to be found from the actual joints affected, or from the order in which they became affected. Thus, a careful history and examination in cases of gonococcal arthritis usually brought to light the fact that the first discomfort appeared in the metatarsophalangeal joints. Similarly, in cases of an intestinal origin, discomfort or limitation of movement was first found in the spine, especially in the region of the lower dorsal vertebrae. These instances could be multiplied and could naturally be used to assist in diagnosis. (2) That the less a joint was free to move the less was electrical treatment likely to be effective unless this could be directed to some central focus, such as the cervix or prostate, or unless the focus had already been discovered and received adequate treatment.

It was obvious that if the physical types to which he had referred showed great differences in their reactions to the stresses of training for flying and required different methods of treatment when they broke down, so would these same types, when affected by disease, require special methods of treatment partly directed to improving their basic condition and partly applied to their affected joints. It was, he thought, in the instant recognition of what was required for the type of patient that the genius of the opener of the discussion particularly showed itself. From the electrical treatment point of view Dr Heald tried to secure, in all cases, the closest collaboration with the doctor in charge of the case so that the diseased joints, the focus (if any), and, above all, the physical condition, might be treated as a co-ordinated whole. Since he began to recognize that the underlying physical condition was of prime importance in cases of chronic arthritis, he had tried combined electrical treatments with considerably improved results as regards the group classification, one part of the combined treatment being directed to the patient as a type, the other to the existing condition. Thus, greatly valuable as the Cunningham and Robinson method was in cases of chronic gonorrhoeal arthritis, the results could be definitely improved in the nervous instability type of patient by combining ultra-violet light baths with the diathermy treatment. Indeed, in the nervous instability class of patient general ultra-violet light treatment in

combination with selected local treatment to the joints materially enhanced the chance of success, while in the cardiovascular debility type diathermy given from the chest behind to the abdomen, with or followed by local joint treatment, had now become for him a routine practice. In the muscular debility type the form of general treatment that produced the most favourable response was either the sinusoidal bath or the rhythmic induced current. In all cases where some form of combined electrical treatment was considered necessary the importance of simultaneous medical measures could not be exaggerated, indeed, it was only the essentially healthy type who, he found, were cured by local electrical treatment only.

Dr Heald then pointed out that the value of electrical treatment should not, in any case, be belittled on the results of cases treated by unqualified individuals, who necessarily could have no knowledge or appreciation of the clinical and pathological factors combined in every case of chronic arthritis, unless such treatment was closely supervised by the physician in charge of the case.

Dr PATRICK WATSON-WILLIAMS (Bristol) said that his experiences had led him to conclude definitely that "focal sepsis," which Dr Mutch had stressed as usually the essential cause of rheumatoid arthritis was at any rate the determining factor in a very large percentage of cases, and that in the recognition of this was the key to the pathogenesis and therapy of this group of diseases. Nevertheless, when treatment came to be considered, it must be realized that often degenerative changes had developed beyond the hope of success following therapeutic measures limited to the elimination of focal sepsis and subinfections, which in course of time might have subsided by auto-immunization while leaving a disastrous legacy of crippling and painful deformity. Then biologically therapeutic measures properly prescribed and carried out afforded most, if not the only, relief. But careful search for the existence of focal sepsis was called for in every case of rheumatoid arthritis, and even in cases of long standing the detection of such a source of infection and its elimination often proved immensely helpful. In an address to the Bath and Bristol Branch of the Association in 1922¹ he had described several such cases, and in the drainage and disinfection of a sphenoidal sinus infection (streptococcal), after many years spent in treatment at various spas, was strikingly successful. In doubtful cases, before directing attention to the bowel, uterus, or urethra, it was well to seek first for such sources of infection in the upper or tract of teeth, because these parts were accessible and the presence or absence of infection there was most readily determined. It was noteworthy that many rheumatoid arthritis cases were nemasthenic, and as there was no more frequent cause of what was called neurasthenia than focal sepsis, it was probably right to attribute the arthritis and neurasthenia to one and the same cause. In the earlier phases of arthritis the patient was often more neurasthenic and depressed than later when the crippling and general condition was more disastrous and distressing. He suggested that this might be due to the earlier depressing effect of focal sepsis being overcome by auto-immunization.

Dr E. P. CUMBERBATCH (London) said that Sir Thomas Horder had remarked that diathermy had its advocates in the treatment of arthritis. The speaker was an advocate of diathermy in the treatment of one form of arthritis—namely, that due to the gonococcus. It was a rational form of treatment, for the reasons that the gonococcus had a low lethal temperature and that the tissues which it infected could be heated en masse by the diathermy current. In order to obtain success the treatment should be applied to the urethra and cervix uteri in females and to the prostate and seminal vesicles in males. The joints themselves need not be included in the treatment. It was all important, however, that the diathermy should be applied with correct technique and in correct dosage. The details of the methods which had been devised by his co-worker Dr Robinson and himself had been recently published in a monograph

¹ Rheumatoid arthritis due to infection of the nasal accessory sinuses. BRITISH MEDICAL JOURNAL, January 21, 1922.

Diathermy could, he believed, be regarded as a specific for gonococcal arthritis in early cases the arthritis could be cured, in advanced cases it could be arrested. In cases of infective arthritis in women the cervix uteri as a focus from which metastatic infection could be disseminated was very frequently overlooked. Endocervicitis, hitherto unsuspected, was often found in women suffering from arthritis. In a few of these cases gonococci had actually been found, in others there had been found coliform organisms, diphtheroid bacilli, or *Streptococci faecales*. In cases of non-gonococcal arthritis it was found that the application of diathermy to the cervix, in some instances, was able to arrest the arthritis, in others it was not successful so far as the arthritis was concerned. But it removed the clinical signs of endocervicitis and the patients' general health improved. Diathermy had been applied to a few patients who were, clinically, cases of rheumatoid arthritis. These patients were young women, apparently virgins, in whom there was no history or evidence of gonococcal infection. In these cases the diathermy was applied by an intra-rectal electrode, and the contents of the pelvis were heated. In some of these cases, though not all, the arthritis was apparently arrested.

Dr DAVID CAMPBELL (Glasgow) said that he would like to draw attention to two great groups of chronic arthritis of unknown origin which were from the pathological point of view quite dissimilar. The first was rheumatoid arthritis, essentially a disease of fibrous tissue. That disease bore on the face of it the stamp of an infective disease. The second type was osteo-arthritis. Here the pathological changes were quite different from those seen in rheumatoid arthritis. These two types should be discussed separately. With regard to osteo-arthritis, very little could be said. So far as he knew, there was no way in which this process, whatever it might be, could be altered or checked. But he was quite convinced that a good deal could be done in the way of amelioration by proper treatment at any spot or by massage. A good deal of the pain was superficial, although so far as he could see there was nothing which could check this pathological change. In rheumatoid arthritis generally, by the time such cases were seen in hospital, there were two quite definite and distinct problems facing the therapist. The one was the orthopaedic problem, the other was the problem of stopping the infective process. He desired on this point to make one observation. In the early stages of the disease the chief factor in causing limitation of movement was pain in the tissues of the joint, or, almost as frequently, in the tissues around the joint. He had seen cases where a knee-joint or wrist joint was put up in plaster, and when the plaster was removed the joint was completely ankylosed, and any attempt to increase the range of movement was associated with great pain and disturbance to the patient. He was convinced that the procedure of splinting in rheumatoid arthritis might be carried too far and do more harm than good. From the beginning the patient should be encouraged to move the affected joint, and if this were done many disastrous sequelae could be prevented or greatly minimized. Next came the question of dealing with the infective joint. He thought that Sir Thomas Horder was guilty of a little mild irony when he suggested that they should treat the cause. The cause was quite unknown. That brought him to the question of focal sepsis, with regard to which he might, perhaps, be allowed a healthy scepticism. The physician used that blessed term "intestinal toxæmia" and saddled the gut with the whole responsibility. He knew that there were cases in which, after the removal of some focus of infection, there was apparent clearing up, but Dr Writtlehouse had stated that in spite of the removal of foci of infection cases were coming to Bath in the same or greater numbers than before. He agreed that if there was any focus of infection it should, on general principles, be removed, but he must express the gravest doubts whether that was really an explanation of the disease. Dr Campbell had treated nearly 200 cases of this disease during the last four or five years and with the exception of three cases, he had not seen any which, on any logical grounds whatever, could be accepted as being due to some focus of infection.

There was no specific drug which could be used. General antiseptics given by the mouth or by ionic medication through the skin could not be got into the blood in sufficient concentration to produce any effect on the organism. With regard to specific vaccines, he did not see how a specific vaccine could be prepared if the cause of the disease was not known. It was a curious commentary on the specificity of treatment by vaccines that in certain diseases such as typhoid and pneumonia, where the causative organism was definitely known, such vaccines were generally admitted not to be in the least efficacious. But lest he should appear as a therapeutic nihilist, he would suggest that some benefit could be obtained from the use of non-specific vaccine therapy—that is to say, protein shock therapy. He did not think this would cure every case—far from it, probably 20 per cent of the cases would show no improvement whatever. A certain number would improve for the time being, but would collapse at a later stage. Out of 70 such cases which he had treated during the last five years, and the last of which left the hospital eighteen months ago, 16 showed no improvement whatever in hospital, 54 were improved, some of them very much so, and out of those 54, 38 had until the present time been able to carry on their work, and had had no recurrence of the disease, in the other 16 the disease had definitely relapsed after periods varying from three to six months or a little longer. Therefore he thought that in cases of rheumatoid arthritis of infective type protein shock therapy was worth trying. He had not observed any case of pleurisy following the use of typhoid vaccine, which was the one he had used, but he had seen two cases which had had albuminuria previous to the injection and developed later a transient hæmaturia.

The PRESIDENT of the Section (Professor Wild) said that he could speak feelingly on the question of infection as a cause of chronic arthritis. He had a condition in his own hands which resulted not from a focal but from a general infection. Some thirty-five years ago he was unfortunate enough to contract a severe attack of scarlet fever in hospital work. At the end of a fortnight his temperature went up again, and he had a very sharp attack of post-scarlatinal rheumatism, with swelling of the joints, in the hands particularly. So far as he knew he got perfectly well in five or six weeks, but years afterwards he gradually noticed the onset of pain and stiffness in the joints of the fingers and the hands. Only those joints were affected that had been primarily involved in the post-scarlatinal rheumatism, he never had any trouble anywhere else. He found an osteo-arthritis developing, with a certain amount of crippling in the fine movements of the hands. He received various treatments, but he could not say that they afforded any particular benefit. It was necessary to make the best of the situation, and to make the hands as useful as might be in the circumstances. None of his colleagues was able to find any focal infection, unfortunately, because that seemed to take away any possibility of permanent cure. But there were one or two points resulting from his experience of the last twenty years which perhaps were worth noting. One thing which had hardly been mentioned in that discussion was the question of climate. The condition of his hands as regards capacity for work depended a good deal upon the weather. By pains in various joints he could foretell the onset of damp weather about twenty-four hours before the barometer fell. Why should an increase in the moisture of the atmosphere cause changes of a sensitive nature to take place in joints that were continually bathed in fluid? The only explanation that he had been able to find was the result of some observations made by a chemist, Dr Thompson of Manchester, during experiments he carried out on the estimation of the amount of carbonic acid in the expired air in the case of mice kept in chambers in which the humidity of the air was varied. When the humidity reached a certain point the elimination of carbonic acid from the body was much diminished. It seemed to the speaker that it was quite possible that one might find in the accumulation of carbonic acid in the body some explanation of the obscure pains. He was rather confirmed in this opinion by the result of experiments on his own diet. He

found that if he took sugar in a little excess this was followed by an increase of joint pains. Everyone was aware of the readiness with which sugar was oxidized in the blood and tissues, and it was possible that so readily oxidizable a carbohydrate as sugar might easily lead to an increase of carbon dioxide in the blood. The questions of climate and of diet were important factors in the treatment of many of these cases of chronic arthritis. With regard to drugs, the only thing that he had found of any use was small doses of thyroid extract for about two or three weeks, this often seemed to be beneficial. Another question was that of movement in joints. He found that the best thing for his own joints was to move them, in spite of the pain. If they were rested too much they were more stiff when he began to try to use them again. The use of them deliberately for work which involved the movements of the joints most affected was often attended, after a day or two's exercise, by a diminution rather than an increase of the pain. He thought that patients should be encouraged to use the joints provided no acute inflammatory symptoms were present at the time.

Dr P. HAMIL (London) thought that in discussing various kinds of treatment there was a little risk of a narrow view being taken owing to enthusiasm for some particular line. There was quite clear evidence that focal infections could play a definite part in causation, but it was well not to be content with one focus. He himself, while in India, had what was reasonably diagnosable as dysenteric arthritis, and it was perfectly clear that there was association between the pain and swelling of certain joints and relapse of colonic discomfort. On coming back to this country from India the same thing occurred from time to time. His dentist could not satisfy himself that there was anything wrong with his teeth, but the x-rays showed the presence of certain abscesses. The offending teeth were removed, and since that date the arthritic discomfort and intestinal instability had greatly diminished. But after a focal sepsis was eradicated there still remained dissemination. If reinforcements could be cut off, the body was able to deal with the army in the field, and this raised the question of both local and general resistance. He thought that cases should be treated on the broadest possible immunological lines. No method which was likely to produce good results should be ruled out. With regard to the question of rest, harm could be done by a too rigid splint, but surely it was one of the first principles that when an organ was acutely inflamed it should be given rest. If a limb were splinted it should not be put in plaster, but the management should be such that a certain amount of exercise and massage could be carried out. He was still unrepentant with regard to his own use of splints in moderation. Another point was to encourage the local nutrition of the joint as much as possible, and here a little exercise and massage were serviceable. The use of thyroid extract and iodides was, no doubt, of some value. With regard to spa treatment, any method which gave the patient comfort and encouragement was useful. The earliest advice on the treatment of osteo arthritis was that given by the prophet Isaiah—to strengthen the weak hands and confirm the feeble knees—that is to say, to exercise and support the muscles.

Dr H. WARRY CROWE (Harrogate) said that it seemed to be agreed that chronic arthritis was almost always infective in origin. If that were so, then surely therapeutic immunization should be successful. In these diseases—arthritis and non-articular rheumatism, for they could be classed together—were found the classical conditions in which vaccines ought to do well. Here was a low-grade chronic infection in which the antibodies of the host were being slowly used up and not rapidly replaced as in acute diseases due to virulent germs. Yet in practice the balance of opinion was unfavourable to this method of treatment. Why should there be this divergence between theory and practice? He believed it to be partly the fault of bacterial technique but not mainly so. The chief fault was with the clinician. The technique of immunization was wrong. Every active case of chronic arthritis under vaccine treatment almost without exception passed through a stage of

sensitiveness to vaccine. Sometimes this was so extreme that vaccines were for a time not tolerated at all. The clinician failed frequently to recognize this state of affairs. At first the patient improved, but a stage soon arrived when he got sensitive. If now the doses were not greatly reduced, failure, even disaster, might result. He did not hesitate to say that when the clinician recognized this fundamental fact his results would be very much better. He would venture the suggestion that this state of sensitiveness was an essential factor in the cure, and that it was only because the patient was insensitive to the low grade erosive organisms that he fell a prey to the disease.

Dr A. P. THOMSON (Birmingham) said that he had come to hear this discussion in order to get help in the solution of the difficult problem of the proper advice to give to a patient with chronic arthritis. He was glad that Sir Thomas Horder had made it clear that the first step was to endeavour to assess in each case, as the result of careful examination, the relative importance of the infective factor. If it were clear that the factor of infection was important, the patient should be urged to submit to the wearisome and expensive investigation that might be necessary to trace its source and to determine its specific treatment. He was bound to say, however, that in the course of consulting practice it was common to meet patients who had been very thoroughly investigated and treated in this way and who had not derived much benefit from the experience. With this considerable group of patients he found himself often in a position of some difficulty, and the principle by which he was guided was simple. It had become clear in the course of the discussion that the general condition of the patient was now recognized by everybody as of extreme importance, and if in an individual case it appeared good he did not hesitate to advise treatment by protein shock. He could not agree with the opener of the discussion that this method should be reserved for the stagnant cases, for, theoretically at any rate, the general stirring up of immunity should be most profitable when the patient had some reserve, and practically the result was sometimes brilliant, though it must unfortunately be admitted that failure was frequent. In the remainder of this group where the general condition was poor and the patient seemed exhausted by pain, worry, and loss of sleep, he first turned to palliative measures of various kinds which he had no doubt were most advantageously applied at a spa like Bath, some of these cases recovered sufficiently to warrant the use of shock therapy later on.

Sir THOMAS HORDER, replying, said that he concurred in the duty of the opener of a discussion not to state with any great bias his own personal views, but simply to outline them, and to give a general review of the subject, that was what he had aimed at doing. The course of the discussion had demonstrated what he had said—that it was not possible to dissociate the treatment of chronic arthritis from considerations of etiology. It followed that in a subject like chronic arthritis, where, as he had expressed it, there was an x factor present, there should be discordant views, both as to etiology and as to treatment. He had his own views, of course, some of them quite strong views, he had his own rules of practice, and so forth, and it had been interesting to him to hear one speaker in the discussion refer to Dr Mitchell's "long hand." Well, in that morning's discussion it might have seemed to be a long hand, but before he (the speaker) was quite so much interested in the clinical manifestations of medicine as he was now there was a time when he spent a good deal of his working day in the pathological laboratory. He had no word to say against the bacteriologist, without whom he could not get along to day, but he thought there was no reason why he should not occasionally "gum" him up. It had been explained to him that the reason why he received these different reports from three bacteriologists with regard to the same material was due to the fact that the material was mislabeled. But was it not the bacteriologist's function to say that the material sent to him was mislabeled? If the bacteriologist himself allowed the material to get mislabeled that was not the fault of the physician sending

the material. As to the diurnal variation, was it not for the bacteriologist to inform him—a mere clinician—that unless he sent him daily specimens for three, five, seven days (it was for him to decide the number), he could not obtain any information to carry conviction to his own mind? These were matters of technique. All his three bacteriological colleagues who sent these differing reports sent him vaccines or were prepared to do so with great conviction as to their benefit to the patient, but they were different vaccines! There must be something wrong, therefore, in the liaison between the bacteriologist and the clinician, and he did not think it was entirely the clinician's fault if that liaison was not as close and as scientific as it might be. He thought that Dr David Campbell was rather moving to the "left"—if he might put it that way—when most of them were moving to the "right," and this seemed a little odd. Dr Campbell appeared to be trying to get cohesion again in that group of arthritics which the rest of them were trying to break up. The more thoroughly they examined the arthritic patient, clinically and bacteriologically, the more convinced they became that this group would be broken up. That there was a residuo they all admitted, whatever name was given to it, it might be well not to give a name at all, or to put the name in quotation marks, so as to prevent misapprehension, but the more they investigated the individual case the more convinced they must be that the infective element was very high. The question as to whether it was a residual infection, whether some of these patients were partly carriers, and for that reason, or partly by reason of their joints being sensitized, got waves of reinfection, was very important,

and it all had a bearing upon the treatment of the individual case. One of the most important contributions to the etiology, and therefore to the therapeutics, was Dr Mutch's reference to the flora of the lower part of the small intestine. Dr Mervyn Gordon and he had previously referred to certain *post-mortem* observations which linked up a little with these very important observations to which Dr Mutch referred. It reminded him of Sir James Mackenzie's lament that so many abdomens were opened and so few scientific observations made, but here was a scientific observation which would be of the utmost value. Dr Mutch had not told them about the question of controls, but there was no doubt that he would report in due course. The types of patients mentioned by Dr Heald were interesting and important. Dr Heald had put somewhat systematically what he (the speaker) referred to loosely when he said that these patients fell into groups as to their nutritional and nerve state quite apart from the infective process. The type of patient should influence not only the choice of local treatment but of general treatment also, but he accepted willingly Dr Thomson's suggestions as to the types of cases in which one should or should not give protein shock. Comment had been made on his remark that the ideal state for protein shock was the stationary case. He did not advise protein shock for the patient who was improving by any other method. Dr Hamill's remarks were also very appropriate. Dr Hamill had taken the wide view which he (the speaker) thought (to come back to his main thesis) the discussion had strengthened—that arthritis was a general disease with local manifestations, and for that reason the patient must be studied quite as much as the joint

ON THE TOXIC NATURE OF THE STROMA OF RED BLOOD CORPUSCLES,

AND A METHOD OF TREATMENT OF BACTERIAL INFECTIONS BASED THEREON *

BY

T. C. CLARE, M.D., B.S., F.R.C.S.,
SURGEON, LEICESTER ROYAL INFIRMARY

THE purpose of this communication is, first, to state, and to support by clinical and experimental evidence, the hypothesis that the constituents of the stroma of red blood corpuscles, when set free into the circulation by the destruction of the cell, have a toxic character and must be regarded as a factor in many diseases, and, secondly, to give an account of a method of treatment based on this hypothesis and designed to immunize the body against this cellular toxin.

Perhaps I can best introduce the subject by briefly relating the circumstances in which the inquiry originated. While on military duty in India I was struck, as all who have experience of tropical diseases must be, by the close clinical resemblance between sudden and severe attacks of malaria and bad cases of heat-stroke. Thinking that there might possibly be a factor common to these two conditions, it occurred to me that the destruction of red corpuscles might be the factor, and that the toxin responsible for the pyrexia in both diseases might be something set free from the red cells by their destruction in large numbers. Two points had to be determined: (1) whether destroyed red cells were actually toxic, (2) whether destruction of red cells could be brought about by the action of the sun. As regards the first point, evidence will be adduced later, but it may be mentioned here that Adams¹ has suggested that the pyrexia of malaria may be due to destruction of red cells rather than to any toxin produced by the parasite itself, and Brown² has shown that haematin causes chills and fever, and has suggested that some, at least, of the symptoms of malaria may be due to the action of haematin formed by the destruction of red cells. In order to decide the second point the following experiment was carried out:

Action of Sunlight on Drythrocytes

On a day when the temperature in the shade was 104° and in the sun 120° (June, North-West Frontier Province) a test tube containing washed human red corpuscles suspended in isotonic saline was exposed to the direct rays of the sun. It was placed in a beaker half-full of water and wrapped round with lint in order to keep the temperature of the fluid approximately that of the wet bulb thermometer. At first every two minutes and afterwards at longer intervals a drop was taken from the surface of the fluid and examined under the microscope in the laboratory a few yards away. A second tube was kept in the shade and used as a control. In the tube exposed to the sun, even after only two minutes, definite changes were observed: many small globules were seen, some adherent to the red cells, others free. The number of these globules was increased in films examined later. In two hours the contents of the tube were chocolate-brown in colour and only a granular debris was seen microscopically, no whole red cells remaining. No change was seen in the control tube.

As the cells were exposed in a glass tube, which would, of course, entirely cut off the actinic rays, allowing only the heat rays to penetrate, the final change, seen after two hours, was undoubtedly due to heat alone, but the changes seen in the first few minutes, before the temperature could have been appreciably raised, were, I believe, due to actinic rays falling directly on the surface of the suspension (the tube being filled nearly to the brim and the sun being nearly vertically overhead).

It is known that ultra-violet light has a haemolytic and, to a less degree, a stromolytic action.³ Details of further experimental work with ultra violet light are given below.

The Toxic Nature of the Stroma of Red Cells

The first experiment to decide this point was carried out on the same day that I first exposed red cells to the sun, and was unsuccessful. The tarry material was allowed to settle at the bottom of the tube and 5 c.cm. of the brown supernatant fluid was injected deeply under the skin. Nothing happened, beyond some discoloration of the skin, and I now know that the toxic element is not soluble in saline but remains in the tarry material consisting of the broken down cells. The supernatant fluid is brown from altered haemoglobin and is not toxic. The other experiments have been done in England.

* A paper read before the Leuceser Medical Society

TOXIC NATURE OF THE STROMA OF RED BLOOD CELLS

[THE BRITISH MEDICAL JOURNAL 641]

Washed red cells, made up to the strength of whole blood, were heated in a water-bath to 56° C for two hours, by which time most of the cells were broken up, and 1 ccm was injected under the skin of the forearm. At the same time the same amount of washed but unheated red cells was injected into the other forearm as a control. Cultures were previously taken to show sterility. The results were as follows. In twelve hours after a pinkish tinge replaced a brownish one. A few hours later the part became swollen and rather tender though not actually painful. This condition remained for about forty-eight hours, when the colour changed and the swelling disappeared, a small hard nodule remaining for several days. There was no appreciable though sometimes the swelling and hyperemia were more marked and lasted longer. As regards the control, there was no general reaction. There was no bruised appearance around the site of injection. No indurated nodule remained afterwards.

The result of this experiment, which has been repeated many times, seemed to me strong evidence of the point I was trying to prove—namely, that the stroma of red cells is toxic to the individual from whom the cells were taken, it is, however, inconclusive, because proteins may be so altered by heat that a non-toxic substance might become toxic by being heated to 56° C. It became necessary, therefore, to use a method free from this objection. In support of this hypothesis I found striking evidence in which he showed, working at the subject from the point of view of the activities of leucocytes, that the stroma of red corpuscles, set free from the cell envelope by grinding in a mortar, was toxic to leucocytes, whether of the same or of another individual. This observation suggested two lines on which to work. First, to isolate the stroma by mechanical means, and, secondly, to use the leucocyte as a criterion of indicator of toxicity in addition to the method of subcutaneous injection.

In all the experiments of which I shall now give a brief account I have had the great advantage of working in association with Mr. Bond, to whom I am indebted as much for his encouragement as for his great technical skill and wide knowledge of the properties of leucocytes. All the experiments with leucocytes have been carried out by Mr. Bond.

I Washed red cells destroyed by heat (56° C) were shown to be toxic to leucocytes as shown by arrest of emigration and by alteration in the iodophil reaction. Unheated cells showed no toxic action.

II Washed red cells ground to a pulpy like debris in a mortar with sterilized silver sand were shown to be toxic to leucocytes and to give rise when injected under the skin to a reaction similar to that described as following the injection of heated cells except that there was no brown staining. As a control in the latter part of the experiment (the supernatant fluid containing haemoglobin was injected under the skin of the other forearm at the same time. No inflammatory reaction occurred but a brown (sunburn tint) stain appeared. (It is remarkable that the clear red solution of haemoglobin resulting from grinding the red cells should produce only the yellow green colour of a bruise.) The supernatant fluid was not toxic to leucocytes.

III Experiment II was repeated substituting powdered glass for the sand and using as a control a suspension of the powdered glass. The same results were obtained but it was found that the glass had a slight inhibitory effect on leucocytes.

IV The experiment was therefore repeated with cells ground without any titrating medium. Complete destruction of cells is tedious by this method and it is difficult to prevent contamination by air borne organisms. The leucotoxic effect was the same as in the preceding experiments and was quite definite.

V Washed red cells were haemolysed by repeated freezing and thawing. No leucotoxic effect was observed.

VI Cells taken by distilled water gave no reaction when injected under the skin.

VII Action of ultra violet light. (1) A thin film of washed red cells was exposed on a slide to a 24 inch water-cooled mercury vapour lamp at a distance of 24 inches. The slide being moved from time to time to ensure a uniform exposure. In three minutes the colour of the fluid had become brownish. Microscopically no changes were observed in the red cells.

(2) 1 ccm of a similar suspension was allowed to fall drop by drop on the surface of a cylinder of ground glass placed at a distance of 24 inches from the lamp. The exposure lasted for one hour though of course, any given part of the film would

actually be exposed for a very small fraction of that time. At the end of an hour the following changes were observed. (a) Haemolysis, few unaltered cells remained but many ghosts and disintegrated cells were seen. (b) The fluid was definitely brown in colour. (c) Examined with the spectroscope a broad band was seen in the position of the typical methaemoglobin band but no oxyhaemoglobin bands could still be seen. (d) The disintegrated cells were shown to be toxic to leucocytes.

As a control in this experiment, cells prepared in the same way were exposed to the lamp for the same length of time and at the same distance, but the quartz lens was covered with a mica film. Beyond slight haemolysis and very slight leucotoxic effect, both evidently due to slight mechanical damage to the cells from frequent dropping on the glass, no changes were observed.

[Mr. C. J. Bond then gave a lantern demonstration illustrating some of the foregoing experiments and gave a more detailed explanation of leucotoxicity. He said:

Some years ago I showed that disintegrated red cells, after grinding in a pestle and mortar, exercise an inhibitory or toxic action upon both native and foreign leucocytes when incubated with them in a closed glass cell. These observations bear on the problem of the reaction produced by the subcutaneous injection of disintegrated red cells. The next step was to show that red cells destroyed by exposure to a temperature of 56° C for two hours, when incubated with whole human blood exercise the same inhibitory and toxic effect on the leucocytes as that exercised by red cells disintegrated by mechanical means. One drop of a suspension of red cells destroyed by heat was incubated with two drops of my own blood in a closed cell for half an hour. On washing away the clot in a gentle stream of normal saline the emigration field of leucocytes on the floor of the cell, instead of forming a thick carpet, was composed of a few isolated cells, some of which showed cytolytic changes. The effect of forming a thick is to prevent the emigration of leucocytes from the incubated clot, and to bring about degenerative changes in the few cells which do emigrate and remain adherent to the slide, it is to this inhibitory and denaturing influence that the term "leucotoxicity" is applied. The experiment has been carried out with different concentrations of red cell debris and with native and foreign blood. Thus the suspension of red cell debris allowed to dry on one half and hour on examination after removal of the clot, a thick carpet of emigrated leucocytes will be found on the print printed with the whole red cells and only a few degenerating leucocytes on the area painted with the disintegrated red cells.

From these and other observations it is, I think, clear that the stroma of disintegrated red cells (not the haemoglobin) exercises an influence on living leucocytes which (1) if not too concentrated inhibits or delays emigration from an incubated blood clot, and (2) in higher concentrations brings about cytolytic changes in the leucocytes which adhere to the slide. There is reason to believe that this toxic property resides in the protein element of the stroma and not in the haemoglobin.

The following clinical observations also have a bearing on the problem of red cell toxicity. I have already shown that if two or three drops of blood taken from the finger of a patient with malaria, during a rigor, be incubated in a closed cell very few leucocytes emigrate from the clot, and those which adhere to the slide show cytolytic changes. This property of emigration is not entirely due to the present during the attack, because if the clot from which the poor crop of leucocytes has been obtained be detached from the slide and gently washed in normal saline and incubated on a fresh slide, a fresh crop of more active cells can be obtained.

I have recently confirmed these findings in several cases of general malaria in which malaria has been induced for therapeutic purposes, and in which the emigration picture

could be observed before the injection of the malarial blood, during the pre-eruptive period, during the administration of quinine, and after recovery.

I have also ascertained that similar conditions obtain in paroxysmal haemoglobinuria. Thus, incubation of blood taken from the finger of a child during an attack gives an emigration picture very like that of malaria during the rigor, only a few degenerating cells adhere to the slide, and this condition remains, in a diminishing degree, for several days after the urino has become clear and free from haemoglobin. Later on, during recovery, free emigration of normal cells occurs. As I have stated elsewhere,² similar conditions are found in certain other diseases, the emigration picture being unlike that seen in pneumonia and some other bacterial infections.

It is evident that the employment of disintegrated red cells as a vaccine in controlled doses with the object of immunizing the body against a toxin of red cell origin is a matter of great interest and importance.]

The toxic nature of the stroma being shown, it is now necessary to inquire by what means red cell destruction is brought about in the body in disease, in order to discover if this toxic agent is of any clinical significance. We have seen that red cells can be destroyed by the rays of the tropical sun, by the ultra-violet light, by heat, and by mechanical means. If it can be shown that bacteria have a similar destructive action the possible importance of this cellular toxin becomes apparent. It is well known that certain bacteria—for example, haemolytic streptococci—have this property.

In order to investigate this matter further I enlisted the co-operation of Dr. Mackrell, pathologist to the Leicester Infirmary, and he very kindly has carried out the following observations.

[Dr. Mackrell gave a demonstration illustrating the haemolytic properties of certain bacteria. He said:

In order to test the action of different bacteria on red cells, tubes containing 5 c.cm. of isotonic broth to which two drops of human blood were added were inoculated with the organism under observation and incubated at 36° C., smears of the deposit were made every few hours. In this way streptococci, *B. coli*, *B. typhosus*, diphtheria bacilli, pneumococci, staphylococci, and diphtherioids, all freshly isolated, were tested. The staphylococci, many virulent strains of which were tested, the typhoid bacillus (isolated from a chronic osteitis), and several strains of diphtherioid bacilli had no apparent effect on the corpuscles, even after forty-eight hours' incubation. *B. coli* isolated from the uterus in a case of puerperal sepsis showed well marked haemolysis in four hours, some isolated from a case of cystitis took twenty-four hours to show haemolysis, while a strain isolated from the faeces caused no haemolysis at all in the first few subcultures, though by repeated subculturing and growing in the presence of human blood it haemolysed as rapidly as the one obtained from the uterus. Diphtheria bacilli caused haemolysis within twelve hours, and pneumococci took a little longer.

In all these cases a diffusion of the haemoglobin took place before the actual destruction of the cell envelope, and the haemoglobin was apparently unchanged. In the case of the streptococcus the action is somewhat different, the red cell being first broken up and the haemoglobin being altered so that the broth has a brownish tinge. These experiments tend to show that many organisms, not only the well known haemolytic ones, act upon red cells and destroy them, and probably produce some, at least of their effect in the body by this means.

There remains the much more difficult problem of demonstrating the presence of an immune body in the serum of normal individuals who have received a series of injections of destroyed red cells, and of patients suffering from diseases associated with blood destruction.

Various methods of complement fixation were tried, using the patient's serum as the specific serum, the antigens tried were (1) a suspension of cells destroyed by heat, (2) an alcoholic extract of red cells, and (3) an acetone extract. The results have so far been negative, though in a case of malaria (benign tertian, before administration of quinine) a deviation of two minimal haemolytic doses

was constantly obtained with each antigen. In two cases of pernicious anaemia the results were inconclusive, as on that occasion the antigen itself was incomplementary. On the whole the results so far obtained have proved disappointing, but the failure is quite possibly due to the method of preparing the antigen. Further work will be done upon it.]

CLINICAL APPLICATION

We now come to the clinical application of the theory which I have endeavoured to put forward. If it is true that bacteria can destroy red cells and that the effect of such destruction is to set free a cellular toxin into the circulation, one may look upon a bacterial infection as having a dual pathogenic effect—first, the effect of the specific toxin of the organism concerned, and secondly, the effect of the endocellular toxin. It may be impossible definitely to distinguish the effects of one of these factors from those of the other, but we may perhaps assume, from what we know of the results of rapid red cell destruction in malaria, that pneumonia, generally observed in most infectious, is due, at least in part, to the endocellular toxin. The method of treatment that I have devised and practised is based on the view that the natural defensive powers of the body are in most cases adequate to deal with the bacterial invasion, but that they are handicapped and sometimes rendered ineffective by the debilitating effects of this secondary pathological factor. I am, therefore, at immunizing the body against this toxin, just as by bacterial vaccines we aim at immunizing the body against the bacterial toxin. There is no reason why the two methods should not be used in conjunction, but I have hitherto not used this combined method, except in a few cases, because of the difficulty of interpreting the results. The method of bringing about this immunization is by the subcutaneous injection, at regular intervals, of a suspension of red cells destroyed by heating them for two hours at 56° C.

The method of preparing the material for injection is as follows.

Twenty cubic centimetres of blood are drawn from a vein into a sterile bottle containing 10 c.cm. of citrated saline to which 0.5 per cent of phenol is added as an additional safeguard against contamination. (In the experiments with leucocytes the phenol was omitted.) The red cells are thrown down by centrifugalization and the serum and citrate solution replaced by sterile normal saline and made up to 20 c.cm. The suspension of red cells is then put up in ampoules containing 1 c.cm., and the ampoules heated to 56° C. for at least two hours in a thermostat. A slightly lower temperature fails to destroy all the cells. A higher temperature results in a sticky fluid which will, with difficulty, pass through a hypodermic needle. One cubic centimetre is sufficient to set up a moderate local reaction when I have used more I have had a rather severe reaction.

I have in all cases kept to the same dose throughout a course of treatment, though it may quite possibly prove to be an advantage to increase the dose gradually. In acute cases the injection is given every three or four days, in chronic cases once a week. Children receive a small dose. As a general rule it is convenient and perhaps advisable to use the patient's own blood, though often, especially in children, it is more convenient to use one's own or my healthy blood. Mr. Bond's experiments seem to show that there is little difference in toxicity, whether the patient's own cells or those of another individual are used, though homologous cells are perhaps slightly more toxic.

RESULTS OF TREATMENT

To test the effect of this method of treatment I have tried, as far as possible, to select cases where patients were suffering from bacterial infections against which they were making no headway, where surgical treatment had failed to bring about recovery, and where no other treatment suggested itself as likely to be of value. Up to the present I have not used it in cases where other methods are being used, because of the difficulty of interpreting the results, and consequently have not used it in puerperal fever or other very acute infections. Suitable test cases are not very common in the surgical wards and out-patient department.

Tuberculosis

Tuberculosis of the urinary tract unsuitable for surgical treatment seemed to me to provide the most severe test of the efficacy of the method, being a disease where the

tendency to natural cure is slight and where the progress can be observed by bacteriological as well as clinical evidence. I have treated six such cases, two of which have only recently come under treatment and are therefore not reported here.

CASE I

A woman aged 28 with tuberculosis of the urinary tract had been in a sanatorium for six months, and afterwards had had a course of tuberculin injections for another six months. When examined she had severe cystitis, tubercle bacilli were present in large numbers in the urine and catheterization of the ureters showed that both kidneys were affected. There was an associated coccal infection. The symptoms were pyuria, occasional haematuria, painful and frequent micturition and pyrexia. Treatment by injection of destroyed red cells (her own) was begun and continued at weekly intervals for twenty-four weeks with an interval of four weeks after the first three months. Improvement though gradual was continuous and definite tubercle bacilli could not be found in the urine after three months' treatment and have not been found since though searched for many times. Her general health has improved greatly and she is able to do her ordinary work. She has had no other treatment except a short course of lavage of the bladder to clear up some cystitis that remained. It is now two years since treatment was begun.

CASE II

A woman aged 47 gave a history of painful and frequent micturition for some months with increasing debility. Cystoscopy revealed a ragged ulcer on the right wall of the bladder and some general cystitis, partly obscuring the ureteric orifices. Tubercle bacilli were found in the urine. After twelve weekly injections tubercle bacilli could no longer be found, and have not been found since though searched for several times. Treatment was stopped but resumed a few months later as pain on micturition was complained of. She had eight more weekly injections after which no urinary symptoms were present. I had occasion to treat her a year later for uterine haemorrhage and examined the bladder. No trace of the ulcer could be seen and the bladder appeared to be healthy. Treatment was begun in July 1923, at the first examination of urine in January 1925, no tubercle bacilli were found, but pus cells and staphylococci were still present in the urine.

CASE III

A man aged 48 whose right testis had been removed three years previously for tuberculous disease. He was admitted on account of occasional haematuria and some frequency of micturition but no pain, tubercle bacilli were found in the urine. There was also a discharging sinus from a tuberculous focus in the sternum of some four months' duration. The patient was a healthy looking man though he had lost weight. He has now had weekly injections for three months and is still under treatment. Tubercle bacilli are still present but his general health has improved remarkably and he has put on nearly a stone in weight. The focus in the sternum has apparently completely healed. The ureters were not catheterized on account of the orifices being obscured by general cystitis.

CASE IV

A girl aged 19 with very advanced renal and bladder tuberculosis. After treatment for a few weeks without benefit it was realized that the case was quite hopeless, the patient died very soon after.

Many cases of bone and gland tuberculosis have been treated by this method, but as in all these cases other methods of treatment, local and general, have been employed at the same time, details of particular cases do not carry much weight. One such case may, however, be worth mentioning.

CASE V

A boy aged 13 had tuberculous lesions in a metatarsal bone in each foot. Skiagrams showed evidence of bone disease, a focus in the fleshy part of the nasal septum and a swelling apparently tuberculous in the left wrist. The diagnosis was made only on clinical grounds and on skiagraphic appearances. Local treatment consisted only of immobilization of the wrist and he was kept entirely off his feet. He has had treatment by injections for four months, a very striking improvement in general health with increase in weight was seen soon after the treatment was begun and the local lesions are now nearly healed though there is still slight discharge from the bone foci and a dry granulating area on the septum which will probably require local treatment. He was treated as an out-patient.

Non tuberculous Infections

The following are cases of non-tuberculous infections treated by this method.

CASE VI

A male aged 18 with persistent pyrexia and metastatic abscesses following operation for suppurative appendicitis. For a month after operation temperatures varying from 101° to 104° were recorded daily, and several metastatic abscesses were opened. After the second injection definite improvement was observed, the temperature rising only once to 101° the third injection was followed by almost normal temperature 100° being recorded once. Six injections were given the temperature remaining normal after the fourth. At the same time the improvement in the general condition was most striking and the abdominal wound previous to sluggish and discharging healed rapidly. The injections were given every four days.

CASE VII

A female child, aged 5 was admitted with empyema. She was suffering also from pychitis (*B. coli*) and had a mitral systolic bruit apparently organic. After thoracotomy and drainage the temperature still remained irregular and a second collection of pus in the chest was drained without effect on it. A month after the operation the child was very gravely ill, the temperature being 103° to 104° daily. After the second injection (three days' interval) a striking fall in the temperature was observed and except for a sudden rise to 103° for a few hours a week later the chart remained almost normal for a month and a very marked improvement in general health coincided with the disappearance of the pyrexia. As the temperature again became irregular for a few days two more injections (0.5 c.c.) were given, with the same result as before. Some pus cells still remained in the urine when the patient was discharged.

These are examples of cases treated on the surgical side, but it must be acknowledged that there have been failures. A case of pulmonary infection after operation for perforated gastric ulcer and a case of actinomycosis, among others, were not benefited in any way. Also some cases of multiple sinuses from bone necrosis of very long standing, which I have been allowed to treat by the courtesy of the officers in charge of the Pensions Hospital, Leicester, have not shown any material improvement. By the courtesy of my medical colleagues I have treated a few medical cases.

CASE VIII—Persistent Urticaria

A man aged 27 had suffered since 1917 from troublesome urticaria affecting the skin of the limbs and face and quite unresponsive to treatment. It had appeared during military service and he was drawing a pension for it. After seven injections (weekly intervals) the attacks had ceased and had not recurred several months after, since when I have lost sight of him.

A case of "urticaria dermatographica" was not influenced by a course of injections.

CASE IX—Pulmonary Tuberculosis

A man aged 56 whose general condition was fairly good presented evident signs in the lungs and tubercle bacilli in the sputum. For some reason he had refused to remain in a sanatorium for more than a few weeks. After treatment by injections for four months no tubercle bacilli were found in the sputum after two examinations and his general health had improved.

Though this case is mentioned I do not, of course, claim that this method of treatment is applicable to pulmonary tuberculosis, though on general grounds it might be considered to be worthy of a more extended trial.

My hope that general paralysis might reasonably be expected to be favourably affected by this method of treatment was based on the now well known results of treating general paralysis by infecting the patient with the malaria parasite. I suggest that this "treatment by malaria" really amounts to a periodical intravenous injection of destroyed cells, and that the beneficial effects are due to an immunizing reaction against this cellular toxin in the way that I have described. A patient was referred to me as being, clinically, quite definitely a case of general paralysis, though no Wassermann test had been done (he was not a hospital patient). After eight injections the improvement in mental and general condition was quite definite, and, I am told, has been maintained, though partial lack of bladder control remains.

HELIO THERAPY

I believe there are strong grounds for regarding heliotherapy, as carried out with such success by Professor Rollier in Switzerland and Sir Henry Gray in Hampshire, as being really a method of application of the treatment by immunization. I suggest that the mode of action of heliotherapy is briefly as follows: (1) Although it has not been proved that the tubercle bacillus has a hemolytic property, like many other pathogenic bacteria, it is probable that the pyrexia, anaemia, and debility are due, in part, to the endocellular toxin. The natural defensive powers of the body are capable, up to a point, of dealing with the tubercle bacillus but are handicapped by the action of this toxin. (2) The sun's rays destroy a certain number of red cells in the superficial capillaries, probably first destroying the endothelial cells forming the capillaries. (The bronzing of the skin may be evidence of blood destruction, but this is uncertain, it is well known that those patients do well whose skin bronzes readily.) (3) The destruction of red cells in the skin sets free a small amount of the endocellular

toxin which acts as an immunizing agent, being favourably placed for acting in this way.

The process of exposure to the sun must be gradual or a dangerous reaction may be set up, the explanation of this is, I think, that the destruction of a large number of cells, before immunity to the toxin has been set up, results in the formation of an excess of the same toxin that is already producing the symptoms of the disease, in the same way that an overdose of a vaccine is followed by a severe reaction.

It is impossible to believe that the rays of the sun can have such powers of penetration as to have any direct bactericidal effect on tubercle bacilli deeply situated in a gland or bone. The explanation that I have suggested seems to me to be more probable, and certainly more tangible, than that given by Dr Rosset in Professor Rollier's book on heliotherapy.

The energy given out by the radiations is stored and carried in the blood stream to every part of the body, when liberated it stimulates the intracellular processes of oxidation and reduction.

In this connexion it is of particular interest to note that guinea-pigs inoculated with hæmatopoiphysin require an extraordinary hypersensitiveness to sunlight and ultra-violet rays. I do not know what explanation of the phenomenon has been given, but I believe that it may be regarded as an anaphylactic reaction, the hæmatopoiphysin (a derivative of red blood cells) sensitizing these animals so that a subsequent dose of a similar or closely allied substance, liberated by the destructive action of sunlight on red cells, rapidly produces toxic symptoms.

SUMMARY

It is well known that the red corpuscles of animals of one species are toxic to animals of another species, Vedder⁶ has shown that human red cell stroma, freed from hæmoglobin, is exceedingly toxic to rabbits. In this communication an attempt has been made to show that the stroma of human red cells, when disintegrated by heat or by mechanical means, is toxic to the individual from whom the blood was withdrawn and to other individuals, it is also shown that many bacteria have a disintegrative effect on red cells. It is inferred therefrom that this endocellular toxin is a factor in causing the manifestations of bacterial infections, and a method of treatment is suggested based on these deductions and aiming at immunizing the body against this toxin.

The toxin produced by the destruction of red cells is probably an example of a "poison of metabolic origin," such as gastrin, hepatotoxin, etc., though in most cases these toxins have been produced by the injection of the particular cells of one animal into another of a different species. G. Bolton⁷ produced an isogastrotoxin by immunizing the rabbit with the gastric cells of a rabbit, and Ehrlich⁸ has shown that an isohæmolysin might be formed in the goat by the injection of goat's blood which would dissolve the blood of another goat. I am not aware that it has been previously shown that human disintegrated red cells are toxic to the same and other individuals.

Reference must be made to a paper by S. G. Billington,⁹ in which he describes how certain "cocoid bodies" are formed from the red cells when a few drops of blood are added to a tube of distilled water with 0.5 per cent ammonium carbonate and heated to 58° C. These cocoid bodies he regards as possibly allied to or identical with microorganisms, and he has treated a large number of bacterial infections with vaccines prepared from these bodies. I have found that the debris resulting from heating washed red cells in the way I have described consists, microscopically, of similar "cocoid bodies", if the medium is normal saline the spheres are large—about a quarter the size of red cells—while if weak saline, or distilled water, is used they are smaller and have the appearance and often the arrangement (pairs, short chains, etc.) of cocci. Their staining reactions, however, are these red cells.

SOME NOTES ON EPIDEMIC ENCEPHALITIS

BY

A. GARDNER ROBB, M.B., D.P.H.,

VISITING MEDICAL SUPERINTENDENT, BELFAST FEVER HOSPITALS

It is not my intention to attempt to give anything like a complete account of the cases of epidemic encephalitis admitted to the fever hospitals under my care during the very sudden and extensive epidemic in Belfast during the spring and early summer of 1924. I shall merely endeavour to refer to some of the outstanding features of that outbreak, and to give some notes and figures gleaned from my experience of that very large number of cases.

The outbreak began at the end of March, 1924. For the first three weeks the cases were few, about the middle of April there was a sudden large increase in admissions, and cases continued to come in large numbers until the end of June, when the epidemic ceased even more suddenly than it began. This seasonal outbreak coincides exactly with our experience in 1920, the only other year in which there has been any extensive epidemic in Belfast. The total number of cases admitted to the fever hospitals in the outbreak of 1924 was 183.

Differences in the type of attack in the cases in this recent outbreak, compared with the earlier epidemics, have been noted everywhere, but I think much, though not all, of this difference is more apparent than real. The descriptions of the signs and symptoms in the early stages of the disease which have appeared in medical literature are necessarily to a large extent based on observations made on cases after their admission to hospital. Whereas in the earlier outbreaks cases very rarely reached the hospital until lethargic symptoms had developed, in this epidemic the cases were much more quickly diagnosed, and were frequently sent to hospital in the stage of excitement and insomnia. This naturally left with the hospital physician a very different picture of the early signs. I know that, speaking for myself, I did not fully recognize until the outbreak of 1924 the very great diagnostic value of a history of persistent insomnia, mental excitement, and talkativeness at the onset.

SYMPTOMS

The prominent symptoms at the onset of this outbreak were (1) flitting superficial neuralgic pains, (2) nocturnal insomnia, often complete and lasting for several nights, (3) mental excitement and exaltation, great restlessness and talkativeness, a little later came (4) diplopia and other eye signs, (5) muscular twitchings of varying degree, (6) delirium of varying degree, and later still (7) lethargy of varying degree. It is, of course, true that in many cases some of these symptoms were entirely absent.

1. *Neuralgic pains* were reported in the large majority. Common sites were the scalp, over the ears and sides of the neck, often extending over the shoulder and arm, the forearm, the fingers, especially the thumb, over the iliac crests, one or both, occasionally pains in the leg or foot were present at the onset, but more commonly this was later, and often very troublesome, manifestation. In a few cases the first symptom was pain high up in the axillæ, and in some very acute pain in the perineum. In many cases if the painful part were firmly handled the pain was slight or absent, but light touching or stroking was intensely painful.

2. *Nocturnal insomnia* was present in a large majority as a very early sign. Many patients were unable to sleep at all for four, six, or even eight nights.

3. *Mental excitement, restlessness, and talkativeness* were very common at the onset, the talkativeness was particularly striking in many cases seen in the very early stage. In many there was a history that if left alone the patient whistled or sang all through the night and more than one patient after admission to hospital treated the ward to a continuous vocal concert throughout the night.

* Abstr. of a paper read before the Ulster Medical Society on

4 *Diplopia and other Eye Signs*—Diplopia was present in 73 per cent of my cases, generally it was not observed until the second or third day. In some it was the first symptom complained of, but in most of these cases careful inquiry elicited a history of previous weakness and restlessness. Squint, nystagmus, and partial loss of accommodation were frequent. Conjunctivitis was noted in only a small proportion.

5 *Muscular Twitchings*—Here I think there was a marked difference between the recent cases and those seen in former outbreaks. Twitchings, myoclonic jerks, and general choreiform movements were much more commonly seen in this outbreak. They were present to some degree in over 70 per cent of my cases. In many the jerking was mild, confined to the limbs, with, in some, twitchings in the lips, tongue, and eyelids, in these they generally passed off in a few days. In many they were very severe and persisted for weeks or even months. In several the patients looked, at first sight, like severe cases of chorea. In these the skin over all prominent parts was often greatly excoriated from rubbing on the bed and clothes. Myoclonic jerking of the abdominal muscles were common, with or without pain, and often slow in clearing up. In one very severe case the abdominal jerks were still present, at the rate of twenty to the minute, at the end of five months.

6 *Delirium* was noted in 52 per cent, it varied in degree from slight nocturnal mutterings to severe maniacal states somewhat resembling delirium tremens. In several instances it was necessary to sheet the patient down in bed. Hallucinations were noted in several cases.

7 *Lethargy* was present at some stage in 72 per cent, it varied greatly in degree. Generally it appeared in the third or fourth week. In many it was at first only in the daytime, the patient continued wakeful at night. Later it was continuous. In a few cases there was profound coma lasting for weeks, necessitating nasal feeding, etc. In a few lethargy was the first sign observed.

Herpes was noted in 6 per cent, generally on the lips or nostrils, but occasionally at other sites.

Respiratory Disturbances—Attacks of polypnoea were common both in early and late stages. Many showed sudden attacks of very rapid shallow breathing (60, 80, or 100 a minute) lasting from a few minutes to hours, especially during sleep, and often accompanied by pricking.

Polyuria was common. One patient, a woman of 48 with a very severe attack, was at the twelfth week passing 500 to 600 ounces of urine a day, with a specific gravity down to 1002. This rapidly became normal after lumbar puncture.

Cerebrospinal Fluid—Lumbar puncture was made in many cases. Little that varied from the normal was found except an increased sugar content. This increase in the sugar is a valuable diagnostic sign, especially in differentiating from meningitis. If there be no increase in the sugar content the case is almost certainly not epidemic encephalitis. Of course it does not follow that if there is an increase the case is one of encephalitis, but it is one important point in favour of such a diagnosis.

Paralysis—Paralysis or paresis of the facial nerve was noted in only a few cases in this outbreak. In my experience it was much more common in former epidemics. Paralysis of deglutition was also less commonly met with in the recent cases.

House Distribution—In very few instances had we more than one case from one house. No member of the staff at either hospital contracted the disease.

Encephalitis during Pregnancy—In the earlier outbreaks of encephalitis it was, I think, the general opinion that, if the disease occurred in a pregnant woman, the outlook was very grave. Very high mortality rates, even as high as 60 per cent, were recorded. In an early report of the Ministry of Health the death rate in such cases was given as 44 per cent. Larger experience has tended to modify this view, and evidence is gradually accumulating

that these high rates of mortality were exceptional, later records show a very much lower death rate. Among the 183 cases in our fever hospitals last spring there were ten cases in pregnant women, with one death—a mortality rate of 10 per cent, this is lower than the case mortality in the whole series (11.4 per cent). In only one of my cases was the pregnancy interrupted, although many were very severe. Two children born in hospital were healthy and have remained so.

PROGNOSIS

In the earlier epidemics in Britain, the Continent, and America, in the years 1918 to 1921, the case mortality rates, calculated on the deaths in the acute stage, were everywhere high—up to 50 per cent in some places. In the report of the Ministry of Health for 1919-20, which dealt with over 1,200 cases, the mortality was 48 per cent. Such figures are certainly misleading, they are arrived at by taking the number of cases notified and the total deaths certified. Everyone interested in the subject knows that, especially in the earlier years, large numbers of cases escaped notification. Professor Hall, in his very excellent work on *Epidemic Encephalitis*, published last year, says: "One may say that in every 100 cases 25 die, 25 recover practically completely, whilst 50 recover with residua", adding that "Such a statement can only be taken as very crude." With larger experience the death rate in the acute stage is gradually being placed lower. In the 183 cases in the hospitals under my care in the spring of 1924 the case mortality was 11.4 per cent. It is very difficult to calculate the correct mortality rate—so many cases recover completely, or almost completely, for a time, some for a few weeks, some for months, and some for years but sooner or later develop serious after-effects which prove fatal.

Percentage of Complete Recovery—Very varying estimates have been given. After our first epidemic waves had passed I think the general opinion was that, roughly, 20 per cent recovered completely. I have always been very sceptical about this recovery rate. As a result of further experience there has been a tendency to put this percentage lower and lower. My own belief is that the percentage of complete and permanent recovery is very small. In a recent discussion on encephalitis in one of the large cities in England the physician who opened it placed the complete recovery rate at 50 per cent, but some of the subsequent speakers questioned this. I think such a complete recovery rate must be very exceptional. My own belief is that if we were to put the percentage of complete recovery at 5 we should at least be much nearer the mark. I am not forgetting that some patients which I had in hospital five or six years ago are still earning their living at their usual occupations and are reported well, but close inquiry has nearly always shown that all is not absolutely well with these patients, and I think that even now, after a lapse of five years it is too soon to sound the "all clear" signal. Riddoch has reported the results in 83 cases which recovered from the acute attack in the London Hospital, they were examined at long intervals after discharge. He found "residua in almost all" (Hall). My own experience coincides with this.

Cause of the Lethargy—The question of the cause of the lethargy cannot be answered at present. Several very ingenious hypotheses have been suggested. I shall briefly refer to a few.

I That the lethargy is due to a "cut out" of the afferent stimuli to the thalamus. There is much to be said for this theory, and it is supported by many authorities whose opinion must carry weight.

II That it is due to changes in the pituitary. Inflammatory changes in the pituitary—congestion, venous thrombosis, and necrosis—have been noted frequently *post mortem*. You will remember that Professor Simmons pointed out the frequent finding of such changes in the autopsies on the earliest cases seen here several years ago. It has been held that under normal conditions the secretion of the pituitary counteracts fatigue. If this is correct

then any inflammatory process which decreases the secretion must increase fatigue and lead to drowsiness, and if there is permanent necrotic destruction this theory would explain the permanent loss of energy which is met with so often as an after-effect in these cases

III That there exists a definite "sleep centre," and that this centre becomes involved in the pathological process. Various authorities put forward this theory, and very different are the sites they suggest for this "sleep centre." Other authorities maintain that the lethargy of epidemic encephalitis has no relation to normal sleep

IV That it is due to blocking of the aqueduct, leading to dilatation of the ventricles with fluid and increased pressure

Whatever may be found to be the true explanation I think it will certainly not prove to be due to blocking of the free passage of cerebro-spinal fluid through the aqueduct. My reasons for saying so are

(1) If a lumbar puncture be made in a case showing deep lethargy and all the fluid which will flow drained off, it will be found that the amount is quite as large as will be obtained from puncture in a case of similar duration which does not show lethargy

(2) If in a deeply lethargic case the puncture be repeated daily the amounts of fluid obtained will be approximately the same, 40 to 60 ccm being the usual amount

(3) If in a deeply lethargic case a lumbar puncture be made and the fluid allowed to flow until only a few drops a minute come away, and if then the patient's head be raised from the pillow and the chin elevated, so as to allow further drainage of the ventricles, the flow through the cannula will immediately increase and a considerable additional amount of fluid will pass off

(4) If in a deeply lethargic infant, with open fontanelles, a lumbar puncture be made, the flow of the fluid can be immediately and markedly increased by pressure on the fontanelle. Removal of the pressure instantly retards the flow, which increases again with renewed pressure on the fontanelle

I have not yet met with a case in which these tests gave any different result, even when the lethargy amounted to complete coma of several weeks' duration. That being so I think that blocking of the aqueduct as the cause of the lethargy may be definitely ruled out

TREATMENT

The course is so irregular, and is subject to such wide fluctuations, such sudden improvement in symptoms, only to be followed by relapses, that it is exceedingly difficult to form anything approaching a correct opinion on the results obtained by any line of treatment. This being so, it is only natural to find in the medical journals from time to time very glowing and enthusiastic accounts of the results obtained by some new (or often very old) therapeutic measure

Many of the treatments suggested, and even enthusiastically recommended, can only be described as weird in the extreme. Let I fancy most of us who have been called upon to treat any considerable number of cases have, doubtfully, employed some of these extraordinary treatments, the rationale of which we could not see, only quickly to abandon them

[Dr Robb then reported his results with very many lines of treatment. He was not satisfied he obtained any good results with hexamine, sodium salicylate, "fixation abscess", diphtheria antitoxin, intravenous injections of the patient's own cerebro spinal fluid, frequently repeated lumbar puncture and drainage, intramuscular injections of sterilized milk, and intravenous injections of "argotropon" (1 per cent colloidal silver and 20 per cent hexamine), as suggested by Marburg and favourably reported upon by Professor Wimmer. Marked relief in chronic cases of Parkinsonism and disturbance of sleep followed the continued administration of 1/100 grain of hyosine hydrobromide three times a day by the mouth, but it was not curative, and the symptoms quickly returned on suspension of the treatment.]

Concluding, Dr Robb said

As a result of my experience in attempting to treat these cases I find myself in complete accord with Professor Hall when he says

"At present any reliable therapeutics, either for the disorder itself or for its many after-results, does not exist"

At the same time it is true that a great deal can be done to relieve the very many present troubles these patients suffer from by the judicious use of palliative measures

ENCYSTED PLEURAL EFFUSION CONTAINING CHOLESTERIN

BY

E O A SINGER, M B, AND E V WHITBY, M B,
M R C P, CAPTAIN R A M C D M R E, MAJOR R A M C

The following case may be of interest on account of the unusual occurrence of a large amount of cholesterol in an encysted pleural effusion

Corporal N, aged 34 years came under our care at the British Station Hospital, Rawalpindi, towards the end of March 1924. He was complaining of pain in the left side of the chest due to fibrinous pleurisy on that side. There were no symptoms pointing to any lesion on the right side of the chest. Examination however, showed an area of dullness extending to about two inches above the liver dullness in the right axilla. This dull area fell short of the spinal column by about two and a half inches posteriorly. The breath sounds were diminished. The heart was not displaced. The temperature was normal, and there was no expectoration.

Paracentesis followed by aspiration was performed, and 25 ounces of a brownish shimmering fluid were withdrawn. It contained crystals of cholesterol. No organisms were found nor hooklets of *Taenia echinococcus*. A culture was sterile. A differential blood count gave the following result

Polymorphonuclear leucocytes	69 per cent
Lymphocytes	24 "
Large mononuclears	4 "
Eosinophils	2 "
Basophils	1 "

The urine showed no abnormality. Nothing could be found to account for the presence of the large amount of cholesterol in the pleural effusion. There was no history of any lung or liver trouble, or of dysentery.

The patient was later transferred to a hospital in a hill station for further treatment, and was discharged from there as a convalescent to light duty. He again came under our observation early in January, 1925. He was then feeling fairly well but complained of breathlessness on exertion, and inability to do any heavy work. The heart's apex was well inside the nipple line in the fifth left intercostal space the sounds were rather faint. The blood pressure was systolic 136 diastolic 76 mm Hg. The thorax did not move freely on respiration. No abnormality was noted in the left lung but there was moderate dullness in the right axilla as high as the third rib, posteriorly it reached to within two inches of the spinal column. The breath sounds over the dull area were faint, there were no accompaniments, vocal resonance was diminished and slightly egophony.

Paracentesis and aspiration were again performed, and 30 ounces of fluid very similar in appearance to that obtained on the previous occasion were withdrawn.

Pathological Report.—Smear negative to the tubercle bacillus. Culture sterile. Fluid contains a large quantity of cholesterol crystals. Some dullness remained after aspiration, and this showed a tendency towards increase. A fortnight later a second aspiration was performed and a further 7 ounces of fluid were withdrawn.

Throughout the patient's stay in hospital the temperature was normal. There was no wasting and no glandular enlargement. There was no increase in the respiration rate while the patient was at rest. The pulse varied from 68 to 100. The urine showed no abnormality.

X ray examination on April 3rd, 1924, showed that at the base of the right chest there was a very dense shadow with a well marked, sharply defined upper margin, suggestive of an encysted empyema. The root shadows were heavy with some slight increase of linear markings in both lung fields. There was no displacement of the heart which was central and dystrophic. There was some impairment of excursion of the right diaphragm. After aspiration of fluid the upper margin of shadow was still well defined, but collapsed to the side of the chest.

General Observations on the Case

1 No cause was discoverable to account for the presence of the cholesterol in the pleural fluid

2 The effusion showed a marked tendency towards recurrence

3 The effusion was encysted, and there was no apparent connexion with the liver

4 In spite of very considerable effusion there was no displacement of the heart

INFECTED MYOMA COMPLICATING PREGNANCY CIRCULAR SECTION FOLLOWED BY TOTAL ABDOMINAL HYSTERECTOMY

HERBERT R. SPENCER, M.D., B.S., F.R.C.P.,
CONSULTING OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE
HOSPITAL

The case here recorded is published to complete my series of Caesarean sections followed by hysterectomy for myoma myomectomy, but the infection of the tumour would have rendered myomectomy or simple Caesarean section a dangerous operation.

M.S., a primigravida, aged 28, married five years, was admitted to University College Hospital on June 12th, 1924.

Menstruation had always been regular every four weeks was free from shreds or clots lasted three to four days and required the use of two or three dapers a day. It had always been painful and had occurred for the first time on September 24th, 1923. The patient complained of frequent and painful micturition and of continuous pain in the lower abdomen and in the left or right side according to her position in bed. The heart and lungs appeared to be normal. The abdomen was enormously distended owing to an excessive amount of liquor amni. The foetus was in the first vertex position the head above the brim. On vaginal examination the cervix was found to be displaced somewhat forwards by a firm tumour which at first was taken for a dermoid. On further examination it was not certain that the tumour was not the breech of a second child for the cervix was in the middle of the pelvis and not pushed forwards to the extent it would have been by a dermoid.

In order to clear up the diagnosis a thick sound was passed into the uterus, it went in front of the tumour which was evidently a fibroid of the posterior lower segment. Caesarean section was performed on June 14th, 1924, before the onset of labour. The child, a girl weighing 9 lb 10½ oz, was delivered in 106 seconds and then removed by total abdominal hysterectomy (Doyen's method) being united by a purse-string suture. The vagina was left open up with through and through stitches of silk-worm gut (tied over gauze), silk (continuous for the peritoneum and interrupted for the skin). The operation lasted fifty-two minutes. The wound healed by first intention and the patient made an uninterrupted recovery. The mother suckled the child and left the hospital quite well on July 11th with her child which weighed 10 lb 10 oz. In the post-ter wall of the lower segment was a fibroid measuring 4½ by 4½ by 4 in. The tumour hardened by formalin measuring on section to have a fibrous stroma with a pinkish grey centre and a darker purplish grey zone at the periphery (see Figure). Under the microscope the tumour was a necrobiotic fibromyoma. Immediately after removal it was examined bacteriologically by Dr. Goodhart. The tumour was sutured with a hot iron and then cut into with a sterile knife. Cultures were then taken from its substance; these gave a mixed growth of *Staphylococcus albus* and a diptheroid bacillus.

It is well known that many necrobiotic fibroids are sterile, and can be removed with safety some contain

inert germs, and for these total abdominal hysterectomy is the safest operation. I have removed by that operation from a virgin a myomatous uterus in which the tumours enclosed abscesses containing a pure culture of streptococci, and a simple recovery ensued. On the other hand, a case treated by conservative Caesarean section in which the tumour was infected with the *Bacillus Welchii*, succumbed rapidly to gas gangrene.

My friend Dr. Philip D. Turner has published an admirable case where he saved a patient suffering from infected fibroids by performing total abdominal hysterectomy six hours after labour. His case should be an encouragement to resort to hysterectomy when sepsis develops after myomectomy, or conservative Caesarean section for myoma, has been performed.

The not infrequent presence of infection in myomata points to the necessity of caution in deciding on conservative operations, especially when they are associated with pregnancy. It would be a great help if a rapid bacteriological examination at the time of the operation could definitely decide on the presence and the nature of infection, but I am not sure that bacteriologists will assume this responsibility. The case now published completes the list of my hysterectomies for myoma complicated pregnancy, the other six have been published already. All the seven mothers recovered, and all the children, except one dead before the operation, survived.

The first of the cases, operated on in 1892, was amputated, the stump being treated extraperitoneally, the remaining six were treated by total abdominal hysterectomy, which I have employed exclusively for the removal of the uterus during the last twenty-five years. That twenty-five years' experience has confirmed me in my opinion that total abdominal hysterectomy is superior to "subtotal" in all cases, whether complicated with pregnancy or not and whether infected or not.

The points in which it is superior were mentioned in these columns in 1902. It has amongst others the important advantage that the patient is freed from the danger of malignant disease of the cervical stump. This is a very real danger of which I have

seen six examples, and I have referred to many others in a letter to this Journal, commenting on a paper by Dr. Fletcher Shaw, who had had three cases of cancer of the cervical stump after amputation of the uterus in the course of eighteen months. The following week Dr. Fletcher Shaw replied "I opened this week's Journal in the full expectation of finding a letter from Dr. Herbert Spencer, not was I disappointed. I think however, further discussion had better be left open until I have published my paper in full."

This reply is less enlightening than would be the long-delayed further contribution by Dr. Fletcher Shaw to the discussion in these columns which I learned from a private

Drawing by Mr. Shiells of the hardened uterus in sagittal section showing the tumour and the Caesarean incision

letter from him in September, 1924, he is in a position to make I asked him then privately, and I ask him now publicly, to make it

TREATMENT OF RHEUMATOID ARTHRITIS BY INTRAMUSCULAR INJECTION OF GUAIACOL, IODINE, AND CAMPHOR

BY

S. WATSON SMITH, M.D., CH.B., M.R.C.P. ED.,

BOUPHENOETH

THE result of the intramuscular injection of guaiacol, iodine, and camphor dissolved in oil has been satisfactory in nine cases of rheumatoid arthritis and articular fibrositis, other than the post-infective, gouty, and gonorrhoeal forms. The cases represented each phase of the disease from the early and the subacute to the rigid and deformed chronic case. The disorder is nowadays assumed to result from a chronic auto-toxaemia of alimentary system origin, and treatment is directed at the detoxication of the whole tract, the aim being to control infection, to prevent the formation of toxins, or to limit their absorption.

Of the nine cases mentioned, four had had carefully prepared auto-vaccine administered during many months, with little apparent benefit. All had had the various other methods of treatment usually employed. In one the use of the combined oil was eminently satisfactory, he was a man, aged 55, who for three years had suffered repeated exacerbations, and whose joints were so painful and stiff that he was almost completely helpless. He had twelve doses, ranging from 0.25 c.c. of the oil for the first dose to 1 c.c. after the third injection, each dose was given at an interval of three days, massage and movement were steadily employed during the whole course, the joint movements had become so free that he complained that his limbs "nobbled too much." Two years have passed since he is walking about freely, and declares himself cured. In the case of a woman, aged 35, who was from the first bedridden, and as bad a case as I ever saw, the result was almost equally good, after a month's regular treatment with the oil she was, during the second half of each day, able to move about quite comfortably with the aid of a stick. Three other cases reported definite steady relief, and showed decided improvement in greater freedom from attacks, in diminished pain, and in being able to move about more easily. The remaining four declared slight benefit after a short course of injections, but they hardly had a fair chance because of the short time during which the treatment was in their cases available.

I do not suggest that the oil will displace vaccine or other treatment, but rather that it should be employed along with those other general and local means commonly used. It is likely to be most useful if backed by the other means it commands—such as full diet, carefully chosen so as to fortify and, at the same time, to obviate any putrefactive or fermentative process in the intestine, generous allowance of fluids given night and morning and between meals, with, at all times, alkali added, saline laxatives, colon lavage, which can be quite well carried out in the patient's own home, and kaolin, with an intestinal antiseptic by the mouth especially if there is diarrhoea. For the articular lesions, gentle massage and passive movement, resistance exercise, and ionization, may each be used to get the best out of the oil. In the management of attacks the oil seems to be of great use, especially when the joints are rested by partial or complete immobilization, and other methods such as active hyperaemia are used. It appears to do good in most cases and harm in none. It seems to me that the oil will be of value where vaccine has failed to detoxicate effectively because of some masked or latent focus of infection having been missed or overlooked, though carefully searched for. It may prove particularly useful where an auto-vaccine appears, after prolonged trial, to

have failed. My personal opinion is that if such a presumed carefully prepared vaccine does fail after four months of fair trial, it is waste of time to continue longer with it, either a fresh search should be made or this guaiacol-iodine-camphor substituted. A patient is too often allowed to drift after vaccine has been used unsuccessfully. If, on the other hand, every source of infection can be well controlled or removed, then the oil given into muscularity will, I believe, be the best treatment to overcome the later effects of the toxæmia.

I had previously used an iodized oil, but the result was not good, then a guaiacol iodine oil which was prepared proved to be much too painful and irritating in use. I now use exclusively an oil obtained for me by Dunean, Flockhart and Co. which contains the three drugs, it is non-irritating, is exact as regards strength, and it answers all requirements. It is made up in ampoules, each containing 10 per cent guaiacol, 10 per cent iodine, and 5 per cent camphor added for its analgesic and stimulating effects, these being useful particularly in frail and depressed persons. The injection is given into the gluteus muscle, or, better still, deeply into the vastus externus about the middle of the thigh, a sterile wide bore platinum needle being used, the same procedure is repeated every second or third day, a fresh site being chosen in the same region of the thighs alternately. It is rather important to treat the syringe carefully, a Record answers well, and after use it should be cleansed with, and stored in, methylated spirit. My practice has been to boil the syringe and needle in a small copper sterilizer for ten minutes before going out in the morning, then to lift out the tray containing syringe and needle, and decant off the water. The ampoule of oil is next placed in the sterilizer so that the heat may liquefy the oil, the tray replaced, and the whole carried in the ordinary handbag. The injection can now be made while the syringe and oil are hot and before the patient gets out of bed. The method has the advantage of being handy and time saving. The ampoule should be handled gently—if the oil is split the odious clinging smell and trail of guaiacol will ensue. Future care in its use. Between exacerbations, and to encourage the patient to move about so as to overcome stiffness and adhesions, the injections may equally well be made in the consulting room. Three syringes and three needles may be carried in a tray at the same time, providing syringe and needle are not returned to the sterilizer after use. In no case did I find any serious general reaction or after-effect, there was some pain and stiffness in and around the affected joints twenty-four hours or so after the injection, with malaise and slight rise of temperature, one came to expect it, but it was transient, and there was no evil effect other than this—no discomfort of any consequence from local reaction, in no case did iodism occur. The urine should be tested and, as far as possible, disease of the kidneys excluded before commencing the treatment, and again, occasionally, during its continuance. By intramuscular injection the full measured dose finds its way promptly into the circulation, and no nodule can be felt at the site of injection next day or afterwards. The highest dose given at any one time was 1 c.c., 0.25 c.c. was injected to begin with, and the seal quickly mounted till 1 c.c. was reached, this quantity was then gone on with, being repeated every third day, or, when thought necessary, every second day.

It is well known that rheumatoid arthritis needs prolonged management, and is difficult to treat successfully or expeditiously. Not one of the drugs employed in its treatment is emulsive, guaiacol being the only generally useful one amongst them. The disease is commonest after 40 years of age, in poorer women especially, at a time of life when they should begin to be able to command better health and some rest and leisure, such cases are pathetic to see, and most of them suffer their disability with amazing fortitude.

In those who cannot afford spa treatment, or who, because of the disability consequent upon pain, adhesions, and deformities, are unable to proceed to a hospital outpatient or electrical department for the special methods there available, the method by intramuscular injection of guaiacol-iodine-camphor oil is particularly useful, it is

quite inexpensive. Its further and more extensive use has to be made before the correct and exact dosage in each phase of the disease is confirmed, and before it can be determined which types of the disease are likely to benefit most by its exhibition. I can find no record of its previous use in rheumatoid arthritis. After a few injections there is a strong smell of guaiacol noticeable in the breath, indicating that the drug is being excreted by that channel. For that reason it is possible that an oil containing guaiacol alone, used intramuscularly, might be of use in tuberculosis.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL

PULMONARY EMBOLISM FOLLOWING OPERATION FOR CATARACT

The operations which most commonly give rise to pulmonary embolism are those upon the female genitalia and operations for hernia and appendicitis. Pulmonary embolism following an ophthalmic operation is sufficiently rare to make the following case of interest.

A married woman, aged 62, was admitted to the Stockport Infirmary on July 24th, 1925, suffering from senile cataract in the right eye. She had previously been a healthy woman and nothing abnormal was detected on physical examination.

On July 25th I removed the lens under cocaine anaesthesia. She was kept in bed and made very satisfactory progress until August 1st (eight days after the operation), when in course of conversation with some neighbouring patients, she suddenly collapsed, became very cyanosed and died a few minutes later.

At the autopsy, at which I was assisted by my colleague Mr. Lambert Rogers, we discovered enormous dilatation of the right heart, due to complete occlusion of the left branch of the pulmonary artery and partial occlusion of its main trunk by a large mass of blood clot, partly recent, partly old.

This case is not only of interest because of the infrequency of the condition following eye operations, but also because it appears to lend some support to Mr. Lockhart-Mummery's recent statement that the fatal clot forms, not at the site of operation, but in all probability in the great veins of the lower abdomen, probably partly as a result of stagnation towards the banks (the vein walls) of the venous blood stream, and also of the liberation into the circulation of thrombinase from the site of operation.

I am indebted to Dr. H. V. White, under whose care the patient was admitted, for permission to record the case.

MALIGNANT DISEASE IN NATIVE RACES

In view of the recent discussions on deficiency diseases, the incidence of cancer among native races, and their relation to one another, the following notes regarding the primitive Hadendowa tribes (Fuzzies) of the Sudan may be of interest.

These tribes live an isolated life scattered over a wide area in dry desert country, rising to a maximum of 6,000 feet in the hills along the Red Sea coast. They subsist principally on the milk of the camel, goat, sheep, or cow, supplemented by a small amount of millet and meat. The milk is drunk cold, and the millet and meat cooked. Constipation is very prevalent. They practise circumcision. Deficiency diseases are practically unknown, and diseases particularly aggravated by insufficient diet rare. Malignant disease is very rare. During the last twelve months I have seen in the whole province two cases—one of epithelioma of the vulva, and the other of a malignant parotid tumour, both were verified by the Wellcome Laboratories at Khartoum.

Among Sudanese natives generally, in the Red Sea Province, the commonest form of carcinoma is cancer of the breast. But statistics are of little use as the number of cases is so small. Simple tumours, particularly lipoma and fibroma, are fairly common.

The Hadendowa are a race of disputed origin, probably neither Arab nor negro, so that the rarity of cancer among

Africans would appear to be due to local conditions and diet rather than to racial immunity. It is curious that both cancer and deficiency diseases should be so rare, as the Hadendowa are liable to most ordinary complaints, particularly arthritis, rheumatism, and syphilis.

I am indebted to Dr. Atkey, Director of the Sudan Medical Service, for permission to publish these notes.

SCROTAL HORN

The rarity of cutaneous horns in these days seems to justify reproduction in the JOURNAL of the accompanying photograph of a scrotal horn.

The patient was a workman, aged 72 years, who stated that the horn had grown in two years—a somewhat remarkable history considering the size. The base was $1\frac{1}{2}$ by $1\frac{1}{2}$ inch, and the horn was bifid. There was a sealy condition of the skin at the base of the horn which shows white in the photograph, and a rudimentary horn appeared at the edge of this area. The man had pared away the point of the horn because it was digging into the skin of the scrotum. The appearance of the horn was that of a rough finger nail. There was a hydrocele of long duration on the affected side. The photograph was taken by Dr. Scott of Broxburn.

JOHN F. LANG, M.B., Ch.B.

OVARIAN GROWTH IN AN ABNORMALLY DEVELOPED WOMAN

The unusual state of development presented by the patient whose case is set out below is the reason for placing it on record. The uterus and left ovary were present only as rudimentary bodies showing no trace of development, the left broad ligament also was undeveloped and no Fallopian tube could be felt on that side.

On July 13th a woman aged about 40 attended hospital complaining of a large abdominal swelling and asking for operation. Her history was that the tumour had grown slowly for the last two years. The woman had never menstruated and in the early days of her marriage she had suffered from dyspareunia. On palpation a large tumour was found slightly fixed in the pelvis but otherwise movable, and extending well up above the umbilicus. Further examination revealed normal external genitalia, a vagina which easily admitted two fingers but no trace of the cervix uteri or of the division of the vagina into fornices. Bimanually no uterus could be felt. The woman's breasts were small but a general inclination to stoutness prevented any unduly masculine or undeveloped appearance of the patient.

On July 24th abdominal section was performed and a solid looking growth of the right ovary, which was attached by a thick pedicle to the broad ligament, was removed. Along the outer side of the growth was an apparently normal Fallopian tube. After removal of the growth the rest of the pelvis was explored. The only trace of uterus and left ovary were two bodies the size of peas situated behind the bladder and in the left pelvis for a respectively. The left broad ligament was undeveloped and no Fallopian tube could be felt. In section the removed ovary, which weighed 5½ lb. showed typical fibroid structure.

The patient made an uneventful recovery, and returned home three weeks later.

Reviews.

PHYSIOLOGY OF SEXUAL REPRODUCTION

THE textbook of Dr FRANK H. A. MARSHALL on *The Physiology of Reproduction* is so well known and so highly appreciated that a smaller book on the same lines by the same author is assured of a welcome. It is entitled *An Introduction to Sexual Physiology*,¹ and is designed to meet the needs of biological, medical, and agricultural students. Though the book is not large the subject is dealt with much more fully than in general textbooks of physiology. Much has been learnt in recent years about the physiology of reproduction, and Dr Marshall not only relates it but helps the reader to form an estimate of its value. We have chapters on anatomy, on the maturation of the spermatogenic cells, on the menstrual cycle, on puberty and the climacteric, on pregnancy, parturition and its sequelae, on the internal secretions of the organs of reproduction, on heredity and sex, and on fertility. All these subjects are treated upon a wide basis of comparative anatomy and physiology. Finally there is a section upon the effects of fertility upon population.

The book should be an admirable textbook for students, and is so simply and clearly written and illustrated that it will be of value to all persons of education who desire first-hand information upon such important subjects as many of those enumerated above, particularly perhaps on the effects of internal secretions, heredity, and fertility.

THE HISTOLOGY OF INTRAPERITONEAL ADHESIONS

WERNERSCHLAGER, in a book on the morphology and histogenesis of intraperitoneal adhesions,² gives the results of an exhaustive study of the process of non-specific chronic inflammation of the peritoneum. Starting with a critical examination of the observations and opinions of previous workers and of the literature, he proceeds to describe the results obtained by himself from cultures of peritoneal exudates *in vitro* and from adhesions experimentally produced in rabbits by means of injections of a solution of iodine and by mechanical means. The descriptions of the inflammatory process are exceptionally clear and complete and are illustrated by numerous excellent figures. Among the subjects dealt with of special interest at the present time are the question of the origin of the collagen fibres, the nature of the serous endothelium and its power of preventing the formation of adhesions, and the presence of nerve fibres in the latter.

The author considers that the various forms of leucocyte that migrate into the exudate are of secondary importance in the production of adhesions. The fundamental factors, he holds, are the proliferation of fibroblasts in the subserous layer of the peritoneum and their migration into the fibrous exudate, and the formation of fibroglia fibrils—the precursors of collagen fibres. The subserous layer of the peritoneum is described as undergoing oedematous distension under the influence of the inflammatory irritant, in the oedematous fluid delicate fibrils (fibroglia or precollagen fibrils) make their appearance and extend into the fibrous exudate covering the surface of the peritoneum, and there become converted into collagen fibres. Simultaneously with the formation of fibroglia, a proliferation of fibroblasts occurs in the subserous layer, and the cells migrate into the exudate by what is described as a "gliding" movement along the collagen fibres and the meshes of the fibrous exudate. It will thus be seen that the author does not regard the collagen fibres as being derived from fibroblasts, but as having an independent origin.

On the difficult question of the nature of the serous endothelium the author, notwithstanding the views that have been expressed as to its epithelial origin and embryogenesis, regards its cells as related to those of connective tissue, and more particularly to fibroblasts. He finds that

¹ In *Introductory* by *Physiology* by F. H. A. Marshall, F.R.S. London and New York: Green and Co. 1925. (Demy 8vo 112 pp. net.)
I have searched for it in *Histogenese der intraperitonealen Verklebung* by W. Wernerschlag, Leipzig: F. C. W. Vogel 1924. (Demy 8vo 40 pp. bound M 43.)

fibroblasts may become flattened out on the serous surface and form a layer exactly resembling the normal endothelial layer, on the other hand, the normal endothelial cells may, during the inflammatory new formation of connective tissue, become converted into forms resembling fibroblasts. With regard to the defensive property of the serous endothelium, it is held that, if unimpaired, it prevents the formation of adhesions but since the vitality of the cells is readily affected by the irritant causing the inflammation, this property is practically negligible, an intact layer of injured cells affords no protection. In dealing with the subject of the innervation of adhesions the author refers to the unsatisfactory results frequently obtained with Golgi's silver impregnation method, in tissues which certainly contain nerves these are by no means always revealed by the method. However, in three out of seven instances of experimentally produced adhesions the presence of nerve fibres was satisfactorily demonstrated. They were also found in the adhesions between stomach, omentum, and abdominal wall in a case of second laparotomy for gastric ulcer. Both medullated and non-medullated fibres may be present, and they mainly follow the course of the blood vessels in the adhesions. It is suggested that they form the anatomical substratum of many of the multifarious painful symptoms to which peritoneal adhesions are known to give rise.

THE PSYCHOLOGY OF THE EMOTIONS

As the outcome of an intensive clinical study of manic depressive insanity Dr JOHN T. MACCARTHY has written a volume entitled *The Psychology of Emotion: Morbid and Normal*,³ in which he aims to establish the thesis that the symptoms are explicable on a psychogenetic basis, and also to shed some light on the nature of the emotion generally.

Much of the book is taken up with interesting descriptions of the clinical material upon which the author's theoretical views are based. He finds that the various forms of manic depressive insanity assumes can be divided into stupor reactions, involuntarily melancholia, manic states, anxiety states, depressions and perplexity states, and he describes and discusses his cases in successive chapters under these headings. It is one of the chief aims of the author to demonstrate that the wide range of symptoms observed in these various types of reaction can be regarded as the expression of common psychological processes which give a unity to the whole group. Briefly, he finds the symptom of manic depressive insanity to be due to the flooding of consciousness with repressed and primitive images which deflect interest from reality and which furnish the material for the delusions and hallucinations constituting the content of the psychosis. The behaviour and emotions he regards as logically determined by the imaginary elements which occupy the conscious field, and in this respect manic depressive insanity can be clinically differentiated from dementia praecox, in which the emotional reactions are incongruous with or inadequate to the delusions expressed. Further more, the author discovers a clinical distinction between dementia praecox and manic depressive insanity from the fact that the fantasies in the former are more primitive and infantile than in the latter.

The clinical section of the volume will probably be most helpful to the psychiatrist as it contains a number of useful suggestions for the differentiation of benign from deteriorating psychoses. The consistency or otherwise between thought and emotion is always a most important diagnostic symptom, and the author's suggestions may be regarded as an elaboration of Bleuler's dictum "I suspect in the extreme cases we now no longer ask, Is it manic depressive insanity or schizophrenia? but to what extent manic depressive and to what extent schizophrenia?"

The book as a whole is somewhat difficult to read as the author's treatment of his subject is involved, and it would have been a great advantage if he had found himself able to develop his arguments more briefly and concisely. The views elaborated as to the nature of manic depressive insanity would seem to be descriptive of what occurs rather

³ *The Psychology of Emotion: Morbid and Normal* by John T. MacCarthy, M.D. Hopkins. M.A. Cantab. The International Library of Psychology, Philosophy and Scientific Method. London: Kegan Paul, Trench, Trubner and Co. Ltd. 1925. (Demy 8vo pp. xvi + 539 2s. net.)

than explanatory of why it should. The ideas which invade consciousness in this psychosis are common to all mankind and find delusional expression in most forms of psychosis. Dr MacCurdy's work leaves us very much in the dark as to why in certain persons these ideas of death, unworthiness, poverty, ambition, wealth, and unrestrained eroticism should assume psychotic intensity. Though psychological methods of approach are essential for an understanding of a patient as a person, we cannot but feel that researches into the physical condition of his organism will be more likely to provide an explanation of his disease. There are so many forms of psychosis where mental disturbances are known to be the expression of a disordered organism, that it seems highly probable that the emotional fluctuations of manic depressive insanity are due to delicate biological changes which are at present not understood. It is difficult to ignore the fact that recent investigations into the physical conditions found in dementia praecox have shed considerable light on the abnormal reactions in this disease, and it would now be very difficult to ascribe these to psychogenetic causes.

Though we do not find the theoretical views propounded in this volume altogether convincing, Dr MacCurdy has undoubtedly made a sincere and painstaking effort to understand the strange ideas and abnormal behaviour of mentally disordered patients. His work makes it clear that there is much to be learnt from the investigation of the content of a psychosis, and a careful study of this volume should give the psychiatrist increased insight into his cases.

SURGICAL PATHOLOGY

In the preface to their *Text-Book of Surgical Pathology* MARSHALL and PRYER refer to the paucity of works on this subject in this country. We have many good books on general pathology, but students and teachers are under the necessity of searching through the pages of the textbooks on surgery for the details of surgical pathology, and they will welcome the appearance of this book.

The authors have deemed it unnecessary to incorporate an account of general pathological changes, such as inflammation, they conclude that by the time a student finds it necessary to resort to a work on surgical pathology he will already have become informed about these processes. The various chapters, therefore, deal with the special pathology of the several regions of the body and the organ systems. The lesions are clearly and concisely described, with their immediate consequences, complications, and sequelae. The text is illustrated by a considerable number of figures, many of them being photographs of actual specimens, not a few of them leave something to be desired in point of distinctness, but if a student is wise he will place very little reliance on pictures, however good, but will get his knowledge from the specimens themselves. A special feature of the book is the endeavour made to correlate embryology, anatomy, pathology, and clinical characters. The authors may be congratulated on having carried out this part of their task with considerable success, it will constitute one of the chief attractions of the book, and will, as they suggest, be of particular value to candidates for the higher examinations. Although the book is very complete as regards the subject-matter included in it, its size has, without undue condensation, been kept within moderate bounds, and forms a handy volume which students will find it an advantage to possess.

FATS AND THEIR ABSORPTION

The second edition of *The Fats*,⁵ by Professors LEATHER and RAPER, which has appeared fifteen years after the issue of the first edition gives a full and well written summary of knowledge of these substances. It begins with a general account of the chemistry, extraction, estimation, and physical properties of the fatty acids, fats, and glycerol. After this introduction the physiology of the fats is treated at far greater length than it was in the first edition of the book, a fact which should make it of the greater interest to

the chemist, biochemist, and physiologist alike. The authors note that the formation of fats in the animal body from protein is very difficult to demonstrate, almost all the instances in which this transformation has been supposed to be proven being based on errors of one sort or another.

The well ascertained fact that in the process of intestinal absorption fats are first hydrolysed, and then resynthesized after passage into the epithelial cells of the mucosa, is explained as due either to the need for a mechanism to prevent the absorption of substances such as petroleum that are like the fats, but unsatisfactory for supplying the body's need of energy, or possibly to the necessity for enabling the organism to recombine the fats absorbed into fats or glycerides that are not identical with those in the food. The formation and excretion of "ketone bodies" in all forms of carbohydrate starvation are described, it has been termed "ketogenesis," and the word "antiketogenesis" is used to designate the effect of carbohydrates in inhibiting their formation and the occurrence of acetonaemia, but the mechanism whereby the carbohydrates bring this about remains obscure. The authors define protoplasm as "a complex equilibrated system in which, side by side with colloidal solutions of proteins, fatty components together with cholesterol, though quantitatively less in amount, play a role which it is impossible to say is less essential than theirs."

The volume ends with a bibliography and an adequate index, it may be warmly commended to all students of chemistry and physiology as containing an admirable account of the fats occurring in nature.

COLOUR-BLINDNESS

COLOUR vision is a subject of great theoretical interest to the physicist, the physiologist, and the psychologist, and of practical importance in many trades and occupations, consequently it has inspired a vast literature. The great mass of the papers has been written from the physical standpoint, and written admittedly in support of one of the many theories which from time to time, from before the Christian era to the present day, have been advanced to explain the phenomena met with. Dr MARY COLLINS, in a new book on *Colour-Blindness*,⁶ has set out to investigate the problem purely from the psychological standpoint, avoiding as far as possible a bias for any preconceived theory.

The subject is one of extreme complexity, showing great variations in its individual manifestations. It is a subject, too, which, especially in its psychological aspects, is still in a state of uncertainty, and on which opinions differ widely. The main value, therefore, in the scientific sense, of Dr Collins's work is the detailed and careful record of facts elicited in the systematic examination of ten congenital dichromats showing various degrees of red green colour-blindness. The subjects, moreover, were all university students accustomed to experimental procedures, and therefore may be regarded as fairly to be trusted. As an accurate account of observed facts the investigation will have a permanent place in the literature of the subject.

Of practical value, and of no small interest, is the comparison of the various methods of testing for colour-blindness. This was ostensibly the main object of the investigation, and the importance of the inquiry can be appreciated when we realize the very high proportion of people with abnormal colour vision (35 per cent of males) and the importance of detecting them. Not only does this apply in the stock example of the engine driver who cannot distinguish between red and green, or the doctor who failed to diagnose scarlet fever, or the undertaker who is said to have covered a coffin with bright red in place of black, but in innumerable occupations the disability entailed involves a considerable amount of hardship and confusion both to the subject and to those dependent in one way or another upon his judgements. Dr Collins's observations show the surprising degree of uniformity that can be reached when using different test systems, provided reasonable precautions are taken in their application. She finds the most

⁵ *Text-Book of Surgical Pathology*. By C. Jennings Marshall, M.D. M.R.C.S. Eng. and Alfred Pryer, M.D. Ch.B. Birm. M.R.C.P. 173 figures. 21 net. London: E. Arnold and Co. 1925. (Demy 8vo 1p. 4s.)

⁶ *The Fats*. By J. B. Leather, M.A. M.B. F.R.S. and H. S. Raper, C.B.E. M.B. Ch.B. D.S. Second edition. Monographs on Biochemistry. London and New York: Longman, Green and Co. 1925. (Sup. roy. 8vo pp. vii + 232, 12s. 6d. net.)

⁶ *Colour-Blindness*. By Mary Collins, M.A. B.Ed. Ph.D. With an introduction by Dr James Drever. International Library of Psychology, Philosophy and Scientific Method. London: Kegan Paul, Trench, Trubner and Co., Ltd. New York: Harcourt, Brace and Co. 1925. (Demy 8vo pp. xxx + 237, 10 figures 1 plate 12s. 6d. net.)

uniformly trustworthy of all the methods to be Edridge-Green's lutein test, who has modified Holmgren's wool test by reducing the number of confusion colours and increasing the number of test stems, and, with these improvements, finds this somewhat discredited test the most to be trusted of the simple methods. On the whole the subjective tests are the most trustworthy, this was to be expected since the error no objective control is possible and the examiner is entirely dependent upon the examinee, tests involving comparison are generally the most satisfactory, as here the subject is compelled to furnish some degree of objective evidence of the sensation he is experiencing.

On the theoretical side of the problem the general conclusion is reached that no one of the theories is thoroughly satisfactory, they fit the facts in the extreme forms, but fail to explain the milder cases. Dr DREYER, who writes an introduction, claims that the results obtained tend to support the "opponent colours" theory of Helmholtz. The two results to which greatest attention is drawn are confirmatory. These are, first, the gradation in the degrees of colour-blindness met with, a subject dealt with by R. A. Houston, and reduced to a numerical scale by Abney and Watson, and, secondly, the verification of the occurrence of two neutral bands, one in the red-green and another beyond the spectrum in the complementary purple, which is a necessary and direct corollary of the three components theory of Helmholtz.

The psychological method of approaching this problem is full of pitfalls. Probably in the past it has received too little attention, for the great difficulty in appreciating the true nature of colour-blindness and correlating the experiences of colour defectives with the experiences of normal individuals is undoubtedly psychological. No one "sees" or does not "see" red (a psychological consideration which seems sometimes to have been forgotten in this as in many other works). We experience a sensation which we have learned to interpret as red. The red blind subject experiences a sensation also, but it is impossible for any individual to assess or accurately evaluate the nature of his or any other individual's subjective sensations. The colour-blind appears to have a definite colour system of his own with individual characteristics of interpretation. Our only method of approximate estimation is by the observation of differences in judgement or conduct in the reaction of these abnormal to external stimuli from the judgements we ourselves form, or the reaction of the generality of people to the same stimuli. Therefore we can have no scientifically accurate idea either of the physiological sensations of the colour-blind or of their psychological counterparts.

PORTRAITS OF VESALIUS

MR SPIELMANN is to be heartily congratulated upon his scholarly and exhaustive monograph on the *Iconography of Andreas Vesalius*,¹ for he has produced a book which will assuredly take rank as the most authoritative work on the subject. Mr Spielmann has brought to his task an immense amount of labour, learning, and skill, and throughout the book he has approached the subject in a most temperate and judicious manner. Wedded to no theory, and entirely unbiased, he has examined critically the claim of every known portrait of Vesalius to be regarded as authentic. When his minute examination is concluded the claim to authenticity of the majority of portraits of Vesalius falls inevitably to the ground, and only a mere remnant of really undisputed representations remains.

We now know the precise value to be attached to that multitude of portraits of Vesalius in existence fondly believed by the possessors to be "drawn from life." The great anatomist is not the only distinguished figure in science to whom violence has been done by attaching his name to portraits which by no stretch of imagination could be held to represent him, for Harvey has suffered in the same way, and requires the same able treatment. Indeed, the persistence with which a great

name in science is attached to portraits bearing little or no resemblance to the known authentic portraits of the individual can only be accounted for by the desire of the owner to label the unknown with a high sounding title, owing either to his ambition as a discoverer or to enhance the value of his property. Engravers have sometimes contributed to the fraud, for there is the case of Richard Lower, the physiologist. When he died, and an engraved portrait was demanded, no portrait was found to be in existence, but the engraver was equal to the occasion for he took the engraved portrait of Lovelady, the poet, and substituted the name of Lower in the inscription.

In the case of Vesalius all that is to be known about his various portraits and engravings can be learned from Mr Spielmann's admirable work, and to everyone interested in the subject we can heartily commend the book.

NOTES ON BOOKS

LORD RIDDELL is to journalism as Talfest to wit—he is not only the cause of journalism in others, but is a journalist himself. Give him a subject, or better a book of two or a subject, and he will presently produce you an essay neatly put together containing a great deal of matter in small space and full of shrewd observations, but frequently disclosing the author's own opinion only by implication, if at all. An exception is an essay entitled "Is Britain a Back Number?" It is a spirited reply in the negative. He enumerates the most notable changes in modern life, from steam and the internal combustion engine to wireless, and the most recent discoveries as to the constitution of matter, he includes also the development of humanizing ideas in industry, and shows in passing that he appreciates what has been done in bacteriology, protozoology, and physiology. It is characteristic of his humour to suggest that American millionaires whose lives have been lengthened by golf "should subscribe to a fund to discharge the British debt to America in recognition of what Scotland has done for them." Lord Riddell's first collection of essays was *Some Things that Matter*, his new volume is entitled *More Things that Matter*.²

MR DAVID MASTERS'S little book *New Cancer Facts*³ is addressed to the public and is largely occupied by a collation of Dr Louis Sambon's recent investigations. The first of the five illustrations is a photograph of Dr Louis Sambon sitting on a penny in Iceland, the next three are six pictures illustrative of Dr Sambon's field work in Italy, and the last is intended to represent the microbe of cancer as discovered by Dr James Young, of Edinburgh. Dr Glover, formerly of Toronto, is also mentioned, and Mr Masters believes that the microbe he has described is the same as Dr Young's. It is difficult to believe that a book of this sort can do any good, whereas obviously it can do harm, because it gives a very inaccurate idea of the state of scientific opinion about cancer. Such a jumble of new cancer opinions (not facts) is especially unfair on Dr Sambon, whose careful epidemiological studies deserve much better company.

A pamphlet, which has almost the dimensions of a hand book, on *Radium, its Production and Therapeutic Application*, has been published by Watson and Sons (Electromedical), Ltd., of London, in conjunction with the Radium Belge, of Brussels, whose agents they are in this country. The Belgian house during the last few years has exploited some rich uranium radium deposits in the Belgian Congo, and has established a reduction plant at Oelen, near Antwerp, for extraction and purification. It is stated that about 95 per cent of the world's demand for the element is now supplied from this Central African source. The little book describes, with much interesting detail and illustration, the processes involved in the separation of radium, the character of the radiations, the technique of measurement, standardization, and screening and the nature and use of the subsidiary substances which radium forms in its process of decay, the first of which, of course, is radium emanation. The section on radium as a therapeutic agent suffers from rather unritical optimism, but there is a great deal of interesting matter in the description of the various forms of contact, applications, and accessories, showing how particularized the application of radium has now become. It is curious that in a work so devoted we have been unable to find any mention of means of protection for the radium worker.

³ *New Cancer Facts*. By David Masters. With an introduction by Sir James Cantlie, B.Sc. F.R.C.S. London: J. Lane The Bookers' Head Ltd. 1925. (Cr. 8vo pp. viii + 83. 6 plates. 2s 6d net.)

MEDICAL AND SURGICAL APPLIANCES

A Modification of Tuffier's Thoracotomy Retractor

Mr CECIL P G WAKELEY, FRCS (London) has found Tuffier's thoracotomy retractor unsatisfactory the retraction obtainable being usually inadequate owing to difficulty in opening the blades by means of the thumb crew. Attempts to do this have often resulted in torn gloves. De Quervain's retractor, although mechanically efficient—retraction being controlled by a ratchet or cross handle—is he considers too unwieldy for general use. Messrs Allen and Hanburys have made for Mr Wakeley a modification of Tuffier's retractor fitted with a powerful ratchet screw it is operated by a removable T-shaped key (see illustration). The instrument, he finds, has the advantage of being small and yet sufficiently powerful to give good retraction. Furthermore the key can be removed and does not hamper the operator.

THE MOTOR SHOW.

FEATURES OF INTEREST TO MEDICAL MEN

By H. MASSAC BUIST

A forecast of the general mechanical and price tendencies to be revealed at the opening this week at Olympia, Kensington, of the nineteenth annual International Motor Car Exhibition, promoted by the Society of Motor Manufacturers and Traders, under the patronage of the King, appeared in these columns last week. A tour of the exhibition in the making proves that there is little to add to what was said then, save in matters of detail. For instance, the tendency to introduce middle size overhead valve, six-cylinder engines is further emphasized by the 2,613 c.c.m. overhead camshaft, overhead valve, Austro-Daimler of nominal 19/70 h.p., the construction of this is interesting in that the flywheel is so set as to lag behind the crankshaft and effectively to damp the development of any "period." This car has four speeds forward, anti-rattle rear springs, wire wheels, and four-wheel brakes. The number of six-cylinder engines of moderate size is also increased by the introduction of the £16 tax Waverley, with Meadows engine, Marles steering gear, and double quarter elliptic rear springs, and of the 3,583 c.c.m. side-by-side valve engine, £23 tax Hupmobile, available as a four-seater open car at £425, or as a saloon for £25 more, thus being supplementary to the "straight-eight," and the smallest of the multi-cylinder engines yet sent over from America. Again, in the interval all prices have had to be fixed and announced. Thus the new 14-h.p. side-valve engine £13 tax Hillman described last week will be on sale with four-seater touring body and complete all-weather equipment at £295, a "Special" version being available at £320, while the four-door saloon on this four-wheel braked chassis is listed at £345.

The Redesigned 18 h.p. Six Cylinder Armstrong-Siddley

Among the firms making changes in the design of six-cylinder engines which have been on the market for some years Armstrong-Siddley adopts monobloc construction in the new 18 h.p. engine for the "Mark II" chassis, the R.A.C. rating being 19.8 h.p. and the cylinder volume 2,872 c.c.m. This engine is installed in two types of chassis: one is the well known 18 h.p. type, the other follows the lines of the 14-h.p. machine, but is equipped with the V-fronted cooler common to all the 18-h.p. types. In both models four-wheel brakes are standard equipment and the road springs live axles. The dynamo, the engine starter,

and the carburettor are notably accessible, all the units being placed high. A crankcase breather has been incorporated near the outer extremity of, and within, the offside rear engine bearing arm. A float type oil level indicator the amount of lubricant in the sump. The improved 30-h.p. engine car is shown for the first time, as well as the 14-h.p. type with frame of conventional construction, half-elliptic springs, and four-wheel brakes.

Common sense Six Cylinder Calcott Practice

There is nothing experimental about Mr Leo Shouter's design of the new (nominal 16/50-h.p.) 2,565 c.c.m. inclined side-by-side valve, six-cylinder engine Calcott chassis. It is listed at £400 complete with four-wheel brakes, and characterized by an eminently common-sense use of well proved practice. This engine has B.H.B. type thickening aluminium pistons with split skirts to prevent slap. Pressure lubrication is employed. Though using one jet only, nevertheless the carburettor achieves the effect of the twin type. A slipper type vibration damper is placed in the front end of the crankshaft, so that when vibration would tend to develop the clutchlike action of the spring-loaded flywheel allows it to move microscopically in relation to the crankshaft, thereby damping out any tendency to the reproduction of the reciprocal action of the shaft itself.

Points Concerning Singer Types

Singer does some striking things in the matter of price—for instance, the introduction of a pushrod and rocker operated 1,776 c.c.m. six-cylinder monobloc engine nominal 14/34 h.p. chassis with Rubury front-wheel brakes and saloon body at £375, the tax being £150. The design is notably clean, the crankshaft has three main bearings, a hot-spot is provided, and mechanical lubrication is employed, balloon tyres are furnished. In regard to the well known smaller four-cylinder 10/26 h.p. engine model, the design of the bonnet has been modified and the petrol filler position been made more convenient. Front-wheel brakes have been standardized on the Alford and Alder pattern manufactured under Rubury patents. In this design the cam spindle is at the bottom of the drum and is universally jointed to an actuating rod carried on the axle. The location of the joint and the angle of the rod are such that when cornering a differential braking effect is obtained automatically. The front axle and landing details have been redesigned in conformity with the requirements of the braking system.

1 Four-wheel Braked 14 h.p. Crossley Coach

The 14-h.p. and the 19.6 h.p. side-by-side valve four-cylinder engine Crossley cars now have four-wheel brakes, the lesser machine being available in standard form as an enclosed carriage of the coach type at £455, being in its line a new standard in values for British-built machines. An outstanding novelty presented this year, too, is the departure by this firm from four-cylinder to six-cylinder practice, thereby entering a new market with an overhead valve 2,692 c.c.m. 18/50 h.p. six-cylinder engine chassis. This is shown in stripped condition, and incorporates well proved up to date constructional practice as the result of seraching tests over a long period. It is designed to have a range of travel from walking speed to over a mile a minute on the direct drive, with silent and smooth functioning, also moderate fuel consumption and low traction rating. It is listed complete with five-seater touring body and all weather equipment at £675 only.

Fiat's Wide Range

Though having a factory at Turin with a frontage over a kilometre long nevertheless the Fiat company has built entirely separate works for the production of its £8 tax, 7-h.p., 990.05 c.c.m., overhead valve, four-cylinder engine, centrally controlled, three speed, £185 chassis with 2 ft. 4 in. wheelbase and low-pressure tires. This is its chief novelty this year. At the opposite extreme the company displays a £1,250 Berlina on the £27 tax, six-cylinder, overhead valve 40 h.p. engine chassis of very distinctive design, which is also shown as a torpedo. Of course, the 10/15 h.p.

side valve and the 15/20-h p four cylinder engined types and the 20/30-h p, side-by-side valve, six-cylinder engined types are continued. Chief interest, undoubtedly, centres in the entirely new hydraulically controlled four-wheel brake, 7-h p chassis that is sold with a two seat coupé body and dickey painted grey and upholstered in red leather at £315.

Standard Developments

Standard makes progress in two directions—in offering, on the one hand, cars at still more attractive prices, and, on the other, in presenting them in appreciably developed condition, notably as regards coachwork. Thus the "Coventry" two seat and the "Knowle" four seat types on the 11-h p chassis are available each at £225, the "Piccadilly" saloon on the same chassis costing £30 more, while the "Chalcote" coupé and the "Stratford" five-seater are listed each at £365 and the "Pall Mall" saloon at £450. The larger chassis is fitted with four-wheel brakes, shock-absorbers fore and aft, and improved steering gear. Drop windows with mechanical regulators are available on the new 14 h p open bodywork, and the two-seater is now really a coupé with glass windows. On the lesser chassis the valve gear is now enclosed, a higher and more imposing radiator is furnished, there is a petrol filler outlet underneath the bonnet, and the front springs are stronger. Likewise the bodies have been redesigned and provided with wider seating and higher sides. The equipment is comprehensive, and most ingenious use has been made of mechanical lifters for adjusting the side-screens on these cars, which have smarter lines.

Swift's Rapid Progress

During the last twelve months Swift of Coventry has made extraordinarily rapid progress, Mr. Muri Wild being now works manager. The design has been advanced appreciably, but confined wholly to the application of sound practice. Thus all chassis are now listed with large diameter four-wheel brakes, and the engines have detachable cylinder heads and aluminium pistons. A wholly new chassis now added to this firm's range is the 1,956 c.c.m., side-by-side cobalt-chrome steel valve four-cylinder engined 12/35-h p machine, the latter figure being the power developed by each unit before it is placed in a car frame. Here the crankshaft is driven by helical gears. The gear box is controlled by the driver's right hand and provides four speeds forward. This new car is shown as a bare chassis, also as a five-seat tourer with four doors and as a four/five seat saloon.

Wolsley's Popular Appeal

Wolsley incorporates a four-speed gearbox and a single dry-plate clutch in the 16/35-h p side-by-side valve four-cylinder engined type. The crankshaft engine is now equipped with bob weights to balance each crank pin individually. The 11/22 h p overhead valve four-cylinder engined chassis (altogether a larger car) is presented with radiator, bonnet, and scuttle of more ambitious and improved appearance. For the rest, Vickers's motor manufacturing concern develops the chassis of its three model programme in minor details only, and makes full use of its very ample resources to provide even better coachwork than formerly. Thus the saloon-limousine on the 24/55 h p six-cylinder engined chassis, the dearest vehicle on the list, is priced at £1,300. Four-wheel brakes are fitted as standard to this and to the 16/35-h p model, whereas they are available at £12 10s more on the 11/22-h p type, which last named is offered with four-seat body at £235 complete, plus the cost of four-wheel brake.

The New 9/20-h p Humber Light Car

Humber makes a serious bid to enter the light car market by superseding its 8-h p type by an overhead inlet, side-by-side exhaust valued 1,056 c.c.m. four cylinder monobloc 9/20-h p engined chassis. This car takes full scale four seat four door bodywork with sloping windscreen and celluloid all-weather side-punching equipment. The

right-hand controlled gearbox gives three speeds forward. The pedal leverage of the large diameter contracting band transmission brake at rear of the gearbox is variable it will. Contracting band brakes are also furnished to the drums of the rear wheels. Hartford shock-absorbers are fitted behind Luots grensegun system of lubrication is employed throughout the chassis, which has a wheelbase of 8½ feet. It is listed with four-seat touring body at £260 and as a four-seat saloon at £315. A four door touring body is available on the 12/25 h p chassis, which is now equipped with a wider cone clutch of greater diameter, and which can be furnished with front-wheel brakes at an extra charge of £25, whereas "f.w.b." are standard on the 15/40 h p chassis.

De Dion Bouton Coachwork Schemes

The £10 tax, side valve four cylinder 10/20 h p engined De Dion Bouton chassis with four-wheel brakes and Rudge-Whitworth detachable wire wheels, which was described in these columns last week, is shown with a standard four seat touring body with an adjustable front seat, five lamps, a speedometer, and electrical bulb-horn, a toolbox, and a combined foot rest to the rear seats, together with a hood envelope, price £295. Another of these chassis is shown with London built "H H H" two seat, three quarter type coupé-cabriolet with double sunl dickey, two doors, the windows being fitted with automatic raising and lowering devices. The leather hood folds, and there is an oval window in the back. The equipment is very complete and the price £395. In regard to larger De Dion Bouton models, the £13 tax 12/28 h p overhead valve four-cylinder engined type also has Rudge-Whitworth wire wheels and a London built "H H H" two/four interior seated all-enclosed coupé cabriolet body of a registered design, with two adjustable front seats, two occasional seats, and two exceptionally wide doors. The windscreen is of the V-type, the hood of folding leather, cloth lined. The windows are fitted with mechanical raising and lowering devices, and there is an interior electric light as well as ample accommodation for luggage. The price, complete with all equipment, is £695. Another of these chassis is shown with "H H H" London built four door saloon, with double adjustable front seats, and three windows each side, price £715. The remaining exhibit is a 15/43-h p overhead valve four cylinder engined £16 tax model with London-built "H H H" six seat Pullman landauletto with four wide doors and three windows, mechanically controlled, on each side, the price being £907 as shown. The cost of the chassis is £495.

The New 13-h p Clyno

The new 13 h p four-wheel braked Clyno car, to which reference was made in these columns last week, has a side-by-side valve 1,496 c.c.m. four cylinder engine with a three bearing crankshaft and adjustable tappets. The gearbox, which gives three speeds forward, is mounted on the front end of the torque tube. The particular form of spiral bevel gear employed in the back axle has been evolved by the manufacturers. The front suspension is by half-elliptic springs, a form rendered necessary on account of the equipment of front-wheel brakes. This car is marketed in very complete form as regards accessories at £298 as a four-door saloon, and at £30 less as a four seater, with adjustable front seats in both cases. The folding-head type coupé costs £285, and the two seater £40 less.

Ford cars are, of course, ineligible for display at this exhibition.

Accessories

As usual, the accessories section is almost bewildering in its variety. Those who do not understand how to handle tyres may be interested to know that the way to fit and to take off Dunlop balloon tyres of the wire type is being demonstrated by experts on Stand No 504. These men are competent to answer any questions concerning tyre or wheel equipment problems. The exhibit is a very comprehensive one and includes some efficient non-skid Fort Dunlop made "Warwick" tyres of low selling price.

British Medical Journal.

SATURDAY, OCTOBER 10TH, 1925

RHEUMATOID ARTHRITIS

It is certainly in accordance with 'the eternal fitness of things'—to quote one of Bath's most illustrious frequenters, Henry Fielding—that no small part of the time of the Sections at this year's Annual Meeting should have been taken up by discussions on arthritis. For the treatment of chronic joint disease has been the preoccupation of the physicians of Bath for many generations, and the Sectional authorities were wise in selecting subjects for discussion on which the physicians on the spot are peculiarly well fitted to speak with authority as to the practical outcome of their experiences. Fortunate, too, was the Section of Medicine in its choice of the opener of the discussion, for Sir Humphry Rolleston is distinguished by his wide knowledge, his breadth of view, and the judicial quality of his mind. The text of his paper, together with a full report of the speakers who followed him, was published in our last issue (p. 589). Wisely, as we think, the Section restricted itself to a discussion of the causation and treatment of rheumatoid arthritis, and this restraint was justified, for the opening paper of Sir Humphry Rolleston showed that this subject, narrow as it might seem to be, offered ample field for his survey, and afforded matter for a whole morning's debate.

Attempts at more or less elaborate clinical classification of the forms of chronic rheumatic disease of the joints have been many in the past, but in this country they have been generally abandoned. Osteoarthritis at one end of the scale and rheumatic synovitis at the other are distinct enough, but they merge into one another through so many grades as to make it in a large number of cases impossible to assign them to either category. Sir Humphry at the outset excluded from his survey advanced cases of osteoarthritis, especially in the hip in old people, while admitting that such a condition may be the outcome of rheumatoid arthritis. After laying before his hearers with judicial impartiality the claims of the advocates of various methods of treatment, he refrained from expressing any decided opinion upon them, but—to pursue the judicial metaphor—put five questions to the jury and left the verdict to them. The subsequent speakers to a great extent ignored these questions except the first—namely, 'Is rheumatoid arthritis always infective in origin?'—to which no one ventured to return a categorical answer either in the negative or the affirmative sense, although most of the speakers expressed the opinion more or less strongly that infection was one of the most, if not the most important of the factors in its etiology. Any estimation of the importance of constitution and of disorders of metabolism in the development of the disease was scarcely attempted, but we think that few would deny that in a number of cases constitutional and metabolic disturbance forms a striking feature. It is evident that we must wait satisfactory answers to the opener's questions until long and painstaking research has very greatly increased our knowledge.

As Dr. Rupert Waterhouse pointed out for more than a quarter of a century the septic focus of infection has been accused of causing rheumatoid arthritis, and

treatment by removal of such foci has been carried out on a very large scale, and at the same time great improvement has occurred in the general standard of hygiene of the upper alimentary canal, yet, unhappily, he has not been able to recognize any beneficial effect on the incidence of the disease as manifested in the patients who seek relief at Bath, he states, on the contrary, that his personal impression is that the number of sufferers from crippling arthritis increases year by year. The contribution of Sir Robert Jones on the necessity for movement and the prevention of ankylosis in bad positions met with general acceptance, and it is to be hoped that the importance of this palliative treatment is now more widely recognized than it was a few years ago. The question as to the relation of tuberculosis elsewhere to chronic arthritis met with a general negative. Those speakers who referred to it excluded all connexion between the two except in the problematic creation of a *locus minoris resistentiae*. The tuberculous rheumatism of Poncet and Leriche has never won support in this country, and not much is now heard of it in France.

The field of the discussion in the Section of Therapeutics, of which a report appears in this issue (p. 633) was broader, for, although it was nominally confined to the treatment of chronic arthritis, it dealt in fact with its pathology as well, and Sir Thomas Horder, who opened it, included in his tabular statement chronic arthritis of all kinds—from that due to gonorrhoea at one end of the scale of infectivity to that due to trauma at the other. The discussion, however, limited itself in the main to a consideration of arthritis in association with focal sepsis, a form which the opener tried to distinguish from rheumatoid arthritis, thereby avoiding the difficulty of answering the question whether the latter is always septic in origin. It is acknowledged that the treatment of infective foci, no matter apparently how thorough may fail to check the progress of the disease, but it can in no case be confidently asserted that all such foci have been discovered and dealt with, a vaccine—such as that of the *Micrococcus deformans* of Crowe, of which Sir Humphry Rolleston spoke—may, however, reach the hidden source of trouble and determine a cure. How far disorders of the endocrine glands, such as hypothyroidism, may be primary or secondary causes of arthritis is a question which cannot yet be fully answered, but research in this direction may in the future throw much light on causation and lead to therapeutic advances.

Various forms of irradiation have their records of striking cures, and the treatment by protein shock has its advocates, who have recorded some impressive results. Thus, besides the elimination of septic foci and of all other obvious impediments to the recapture and retention of health there are many means at our disposal and it is to be hoped that no arthritic in the future may be justified in echoing the words in St. Mark's gospel regarding the woman which had in issue of blood twelve years—that she had suffered many things of many physicians and was nothing bettered but rather grew worse. Yet the difficulty is often great of deciding which particular therapeutic measure is best suited to a particular case and the patient may have much to go through before relief is obtained. Nevertheless, the impression made by a study of the reports of these discussions is on the whole encouraging. The various means of treatment which were considered are not antagonistic and the adoption of one does not necessarily counterindicate the use of another. Everyone will admit that septic foci are dangerous, and that

whether there be symptoms of arthritis or not steps should be taken to eliminate these possible sources of disease. Whatever special treatment is decided on, the judicious practitioner will insist on the adoption of the best obtainable hygienic and moral environment, not omitting close attention to diet and the restriction of the carbohydrate intake. Gout and rheumatism are seldom confounded nowadays, but the traditions of former times still exert their influence, and there remains a tendency to restrict the use of meat in the latter disease merely because meat has been found to have a bad effect in the former.

MEDICAL POLICY OF THE COLONIAL OFFICE

In his speeches at the Imperial Social Hygiene Congress this week the Secretary of State for the Colonies has made a declaration of policy of first rate importance. In particular he has stated that he and those with him at headquarters who have to look at such questions as the eradication of tropical disease realize the increasingly important part that medical service has yet to play in the whole scheme of administration in the tropics, and the increasing attention that administrators are bound to devote to the medical aspect of the problem, and again, that his department is considering in what way and in what form the medical side of the Colonial Office can be still further strengthened.

The reorganization of the Colonial Office is, indeed, the necessary complement to the creation of the Civil Research Committee if the ideal of efficient administration is to be realized, since the Colonial Office is the main channel through which the influence of the Research Committee must be brought to bear in a large part of the empire, and as the first field of the committee's activity has been found in public health, so the creation of an adequate medical department at the Colonial Office—a reform long overdue, as we pointed out when Mr. Amery first announced his purpose—is an even more vital necessity now than hitherto. We look, therefore, with anxiety for a more detailed statement as to the scheme now being elaborated. Until the Colonial Office itself gives effect to the principles which it should seek to enforce upon local administrations much of its work must remain nugatory. There is work of the first importance centrally for a distinct medical section, under a medical head, who must have free access on the one hand to all sources of information affecting his work, and on the other to the responsible Minister in charge of the department.

Meanwhile we welcome Mr. Amery's recent statement as an indication that the Colonial Office at last appreciates an aspect of the imperial health problem too often overlooked in the past. Research in tropical diseases is as necessary as ever, but it is unfortunately a fact that in the tropical dependencies execution already lags far behind knowledge. The immediate task before the Colonial Office is to impress upon the local administrations the necessity for maintaining health services adequate in personnel and in material resources, and for adopting a progressive health policy. There has been in some quarters a tendency to regard these services as mainly, if not exclusively, responsible for the health of European officers, and even where this is not so the establishment has too often been wholly inadequate for the discharge of other functions. Even now, when verbal recognition of medicine as a productive service is becoming general,

both the clinical and public health branches of the services are too often understaffed, while health programmes accepted in principle are again and again postponed indefinitely for lack of funds, little heed being paid to the wastefulness of such so-called economy. Beyond this the development of health policy is in some colonies fatally hampered by the absence of a responsible medical head of the health services, and then consequent subordination to lay control. It is conditions such as these which, together with definite inadequacy of remuneration and uncertainty as to future developments, have recently forced the British Medical Association in many instances to dissuade its members from entering upon a career which should be among the most attractive open to a medical practitioner of energy and imagination. The shortage of personnel is, in fact, due not only to mistaken economy, but also to a dearth of suitable candidates. This feature of the situation depends, not, as has been suggested in various official documents, on a "lamentable ignorance among medical students as to the prospects which the Colonial Medical Services hold out," but rather on a correct appreciation of the present limitations of those prospects.

If, however, we may take Mr. Amery's words at their face value, this state of affairs may soon be remedied, for all that is necessary is to secure conditions of service making for efficiency, and to restore the confidence now lacking in the guarantees offered by the Colonial Office. In this task the Secretary of State may depend upon the cordial co-operation of the Association, which has consistently laboured to establish such conditions, and to this end is prepared to place at the Minister's disposal experience derived from a membership which covers the whole of the dependencies under consideration. If the Association's advances have not always been met officially in the spirit in which they were made, it is none the less ready to renew them as occasion offers, recognizing, to quote Mr. Amery's own words at the Congress dinner (reported at page 676 this week), that "not the least of the functions of the Colonial Office is to act as an Imperial Ministry of Health, and that one of its primary tasks is to create enthusiasm for the work of physical regeneration."

INTERNATIONAL CO-OPERATION IN SCIENCE

ONE section of the work of the League of Nations which received prolonged consideration at Geneva during the recent Assembly is that known as intellectual co-operation. A year ago the Assembly authorized the establishment in Paris of an International Institute of Intellectual Co-operation, to be under the control of the League, but subsidized by the French Government. The choice of Paris was criticized at the time because it suggested that France had some pre-eminence in culture, but ultimately the proposal secured something like unanimous approval. The institute has now been definitely constituted, and will be in full working order during the present year. The French Government is supporting it at an estimated annual cost of two million French francs (£20,000). The director is M. Julien Luchaire, inspector-general of public education in France and laureate of the French Academy. M. Luchaire a fortnight ago gave the delegates assembled at Geneva an account of what has been already done and what it is proposed to do. He said that the institute had been organized in seven sections—namely, general relations, university relations, bibliography and science, legal relations, literature, art and information. The chiefs appointed to these sections are respectively an Englishman,

a Pole, a German, a Spaniard, a Chinese (a lady), a Belgian, and an Italian. To the science section a very ambitious programme is committed. In the first place, it will endeavour to organize an international analytical bibliography in all branches of science. So far as physics is concerned, a large number of reviews publish articles on this subject, and there are three reviews which prepare a fairly wide analytical bibliography, but hitherto these have competed uselessly with one another, while being individually incomplete. The Committee on Intellectual Co-operation has had a meeting with the directors of these three publications, and an agreement has been reached whereby, through a division of the work, physicists of all nationalities will have an opportunity of becoming fully and immediately informed of the immense production throughout the world in this branch of science. Another task before this section or the institute is to create a liaison between the libraries of all countries, particularly with a view to arranging specialized centres for the collection of scientific documents. A system for the international loan of books and the exchange of scientific publications is also to be brought into being. Investigations are to take place with a view to the setting up of new international institutes of research, and measures likely to encourage young people devoted to scientific research are to be examined. Then the unification of nomenclature and of standards of measurement in certain sciences is to be attempted, a beginning has already been made with regard to the terms employed in nosology. Another task proposed is the diffusion by means of analytical summaries of scientific work performed by nationals in countries whose language is not widely known. Among the questions referred to the section charged with general affairs is the setting up of an organization for the preparation of youths for international careers. The question had already been considered by the Committee on Intellectual Co-operation sitting at Geneva of the establishment of an international university or an institute of international studies under the auspices of the League, and now the Paris institute is to give the question a more detailed examination. A scheme for study tours and exchange of students of all countries has also been approved. Another proposal, from Rumania, is the flotation of an international loan for the restoration of science in certain countries, particularly those which suffered most severely from the war. The information section of the new institute is to examine questions concerning books—for example, the question of introducing uniformity of size and paper measure, and of undertaking a campaign against the use of papers and inks of inferior quality whereby the printed record is likely in course of time to be destroyed. M. Luchaire concluded his address with an eloquent tribute to M. Henri Bergson, who has been chairman of the Committee on Intellectual Co-operation since its foundation but was unable to go to Geneva this year owing to ill health. He spoke of Bergson as a great citizen of the intellectual world who had devoted all his time during recent years to the work on intellectual co-operation, giving second place even to those philosophical speculations which had been his glory and his delight. A telegram of greeting and homage was sent to M. Bergson from the delegates at Geneva.

THE PREVENTION OF RICKETS

THE discovery of the value of cod liver oil and ultra violet rays in the treatment of rickets has not unnaturally led to the suggestion that these agents may be of still greater service in prevention. In the autumn of 1923 the United States Children's Bureau, jointly with the pediatric department of the Yale School of Medicine, organized an experiment on a large scale with a view to gauging the practical utility of this suggestion. A children's bureau

was set up in a district of the city of New Haven, Connecticut, to deal with a population of about 13,500, one-third of whom were negroes and the remainder American, Italian, Irish, and Polish. The infants born in the district during the first two years of the experiment were examined and put on a course of cod-liver oil and indoor and outdoor sun baths, commencing, if possible, before the end of the first month of life. They were re-examined monthly for any signs of rickets, and intensive treatment was given when found necessary. Control material was provided by the examination of children in the district under 5 years of age at the time when the investigation started, and later on a further control group was provided by children who had not had this preventive treatment for some reason or other, though born in the district since the autumn of 1923. A preliminary report by Dr. Martha M. Eliot of the results obtained up to the present appears in the *Journal of the American Medical Association* for August 29th (p. 656). Of the 216 infants born during the twelve months following August 15th 1923, only 23, or 11 per cent, gave at no time any evidence of rickets, 179, or 83 per cent, were shown radiologically to be suffering from mild rickets before they were 8 months of age, while the remaining 14, or 6 per cent, were found to be rickety only after the age of 8 months. In 90 per cent of the 179 cases rickets was recognizable before the infants were 6 months of age, in 65 per cent before 4 months, and in 12 per cent before 2 months. It was much more difficult to make an early diagnosis of rickets by clinical examination, because the ricket deformities begin as exaggerations of the normal shape of the bones and cartilages. The x-ray diagnosis, therefore, preceded the clinical diagnosis by a considerable interval—a point of obvious practical importance. It is suggested that the high rate of the occurrence of rickets may be looked on as physiological rather than pathological, being due to the growth impetus outstripping the power of calcification. About 75 to 80 per cent of the infants were breast-fed, and the question of the dietary of pregnant mothers is also being studied. Large, rapidly growing breast-fed infants and premature babies seemed in particular to need antirachitic treatment. This "physiological rickets" can, it appears, be prevented from becoming pathological by treatment, if applied early. Experimental work on corresponding lines is being done in New York, Cincinnati, and elsewhere, and this combination of clinical and statistical methods of research should throw light on important problems of medicine and public health.

MYXOEDEMA

ATTENTION was first drawn to this disease in 1873 by Sir William Gull, who described it under the title of "A cretinoid state supervening in adult life in women." Four years later the condition was labelled "myxoedema" by William Ord. The clinical and pathological descriptions given by Ord reawakened the interest in the functions of the thyroid gland, which had been only feebly aroused by Schiff's original thyroidectomy experiments some twenty years before. Schiff returned to his investigations on the thyroid gland in 1884, and was the first to try the effect of transplanting the gland in order to counteract the results of extirpation. Meanwhile, Kochei had been describing his cases of "cricheva strumipriva," which Felix Senon later showed to be identical with those of myxoedema. Fortunately the relief of this condition was not to be dependent on the chance of a successful transplantation, as George Murray was able, in 1891, to cure such a case by injecting a glycerinated extract of the gland—a method soon to be abandoned when it was shown by Howitz in Denmark that results were equally good and infinitely easier to obtain by oral administration of the gland extract raw or cooked. It is those early days of thyroid medication—

days which were ushering in an era of therapeutic resources of apparently endless possibilities—that Dr A A London and Sir Joseph Verco recall in an interesting retrospect of their clinical experiences of myxoedema. Thirty years ago papers were read by them and by Dr T W Corbin (who died in 1922) to the South Australian Branch of the British Medical Association on this subject. Reference to them will be found in the first edition of Allbutt and Rolleston's *System of Medicine*. Dr London recalled the first case which came to his notice, in 1883. On the patient's return to Australia several years afterwards he was able to relieve her symptoms by injecting her with thyroid substance in the manner recommended by Murray. The patient died at the advanced age of 86 of cerebral haemorrhage. That myxoedema did not necessarily shorten life was shown by another case of Dr London's—that of a lady who had been under thyroid treatment for almost a third of a century, and who had attained the age of 91. Several points are suggested to Sir Joseph Verco as an outcome of his last thirty years' experience of myxoedema. Pleading for alertness in recognizing the less usual manifestations of the disease, he urges the necessity of bearing in mind that a menorrhagia or an epilepsy might be due to a myxoedematous state. Such conditions consequently require to be treated, not as substantive diseases, but as manifestations of a thyroid deficiency. In cases of long-standing myxoedema, the true nature of which has not been recognized, the patient may be so ill as to be unable to move about the house or even to rise without flinching. The initial doses should then be small (one or two grains daily), otherwise a catastrophe may result. Very soon the dose can be increased to ten or fifteen grains a day. Again, in myxoedematous patients the thyroid tablets must be taken prominently and regularly, and not to impress this indelibly upon the patient is, he says, a grave dereliction of duty on the part of the doctor.

PHYSIOLOGY AND ORTHOPAEDICS

The ultimate aim of orthopaedic surgery being a restoration of function, a knowledge of the normal function of the body as far as movement and posture are concerned is essential to the orthopaedic surgeon. Mr A S Blundell Bankart, in his presidential address to the Section of Orthopaedics of the Royal Society of Medicine on October 6th, emphasized this by taking as his subject "The physiology of muscular action." He referred first to Sherrington's work on postural activity, which had gone to show that skeletal muscle manifested its activity not only in the phasic, quick, transient contractions associated with voluntary movements, but also in tonic, slow, and prolonged contractions which maintained posture. These functions are physiologically distinct, and, it has been recently suggested, anatomically separate. The changes which a striped muscle fibre undergoes in voluntary contraction or relaxation are essentially chemical in nature, probably associated with some change in surface tension, and certainly accompanied by marked metabolic changes. Voluntary contraction is a tetanus produced by a succession of stimuli each muscle fibre obeying the "all or nothing" law, the degree of muscular contraction depending upon the number of fibres taking part and hence upon the strength of stimulus received. Muscular education is therefore a bad term; remedial exercises educate reflexes. Another term regarded by Mr Bankart as unfortunate is "antagonist"—the muscles on the opposite side of a joint, following the law of reciprocal innervation, really co-operate in any movement. When this reciprocal innervation is absent, as in spastic paralysis, then antagonism is

actually present. The nature of response to stimuli in unstriated muscle is different, being essentially slower and more prolonged, and this is probably due to the fact that the unstriated muscle fibre offers more resistance to the impulse. Such increased resistance or viscosity probably explains the nature of response in a striated muscle in postural activity. Such activity entails practically no increase in metabolism such as occurs in the isochemical changes of voluntary contraction, and is probably therefore a physical change, and in terms of colloids represents a change from sol to gel in the muscle cells. There is therefore no physiological reason why these two activities of striated muscle should be performed by different parts of the individual fibre nor by different fibres. Mr Bankart said that the evidence brought forward by John Hunter in support of the latter theory needs critical examination, in a recent review of the whole subject Walsh had stated that Hunter's experiments and cases are inconclusive. Mr Bankart's own experience in the operation of sympathetic amputation has been that the evidence is all against the sympathetic innervation of certain special muscle fibres concerned with tone. Sherrington has shown that tone is a proprioceptive reflex, and postural deformities are due to a defect in normal postural reflexes. Remedial exercises are used to treat this condition, and if movement and posture are due to separate mechanisms it is difficult to see how the re-education of muscles in respect of movement can improve posture. The recasting of remedial exercises was, Mr Bankart said, long overdue, particularly with reference to resisted movements, which were very valuable, and the posing and posturing of ballet dancing might be successfully imitated. The transplanting of tendons in the lower extremities should only be carried out with a clear idea of the mechanism of postural tone. The application of physiology to orthopaedics opens up a very wide field for investigation, and should go a long way to clearing up much of the uncertainty now existing as to the most appropriate remedial measures.

CHARLES DICKENS'S MULBERRY TREE

In one of the illustrations to Mr Munhead Little's article on the site of the British Medical Association's new House, published in our issue of July 18th (p. 113, Fig. 5), a mulberry tree is represented as standing at the back of Tavistock House, in which Charles Dickens once lived. The photographic original of the illustration was taken about the year 1901, just before the house was pulled down. It shows a well-grown tree standing by itself, but in the four and twenty years that have since elapsed the garden was neglected, and shrubs and other trees were allowed to grow close round the old tree and more or less choke and conceal it, so much so that at the time of the opening it was scarcely to be distinguished from the mass of foliage around it. As the result of representations that were made to the Duke of Bedford's agent, that gentleman consulted his Grace, who gave instructions that the shrubs should be cleared away and a railing placed round the tree. The clearance has now been made, so that from the south garden of the Association's House the tree is clearly visible. Like all good mulberry trees that have reached a respectable age, it is propped up, but less elaborately than Milton's mulberry tree in the grounds of Christ's College, Cambridge. There seems some reason to suppose that in the time of Charles Dickens's tenancy the garden of the house extended further towards Tavistock Place and included the tree. The existing railings do not appear to be old enough to have been erected before Dickens gave up the house in 1860, they are, however, shown in the photograph. The interest in the old tree—it is probably nearly 100 years of age—is sentimental, but such sentiments are widely held, many trees are associated with famous individuals, and

¹ Myxoedema. A Sequel, by Mr A A London M.D. Myxoedema by Sir J Verco M.D. F.R.C.S. (Medical Journal 1924) July 4th 1925)

it is still not unusual to plant trees to commemorate great events or the visits of important persons, therein perhaps unconsciously exhibiting a survival of the tree worship of our primitive forebears which was once world-wide. The old crulpr in Gray's Inn Gardens is associated with the name of Francis Bacon and remembered by the graceful verses which were written of it by J. K. Stephen, albeit the tree can hardly be 300 years old. The names of many other historical or mythical persons which have been associated with venerable trees will no doubt suggest themselves to readers.

MEDICAL LINKS WITH DR JOHNSON

THE celebration on September 19th of the 216th anniversary of the birth of Samuel Johnson brought many distinguished Johnsonian scholars to Lichfield. At the festival supper the toast of "Dr Johnson and his physicians" was proposed by Mr S. C. Roberts, secretary to the syndics of the Cambridge University Press and the author of several books about Johnson, who remarked on the intimate and personal association of the great man with the medical profession from his earliest years. One of his godfathers was a doctor, whose daughter Johnson later took into his household. Another medical associate was a Dr James, whose powders were a favourite household remedy in the eighteenth century, and who published a medical dictionary with the aid of Johnson. Other medical friends mentioned were Lawrence and Bathurst, the latter of whom was described as "a very good hater." Johnson was himself something of an amateur physician and surgeon, and prepared a special mixture by powdering dried orange peel. Towards the end of his life he took an interest, that may have been embarrassing to his attendants, in the surgical treatment of his dropsy. Dr Robert Hutchison, who replied to the toast, gave a lecture on Dr Johnson's doctors at the May social evening of the Royal Society of Medicine (BRITISH MEDICAL JOURNAL, May 9th, 1925, p. 895). On the present occasion he pointed out how far Johnson was ahead in some respects of the medical knowledge of his times, as, for instance, in his disapproval of routine blood letting. One of Johnson's friends, Sir John Flower of Lichfield, had written one of the earliest treatises on asthma, and was a pioneer in the matter of cold baths. In the Ivy Club there were three doctors out of ten members, none of whom was notably successful in medical practice. Included in the literary club, however, were medical members, some of whom attained great eminence, as, for example, Sir Richard Warren, the most successful physician of his day who left £150,000 when he died. Another medical member wrote a good textbook, and was an advocate of one meal a day, though his own daily meal was large and lubricated with a tumbler of strong ale, a pint of brandy, and a bottle of port.

INTERNATIONAL ASSOCIATION OF MEDICAL MUSEUMS

BULLETIN No. XI of the International Association of Medical Museums contains several short communications on museum technique, photography, and microscopic and bacteriological technique. One of the most interesting of these is an article by Dr Maude D. Abbott on the Wyatt Johnson descriptive classification of museum specimens, as applied in the pathological museum of McGill University. We see also that the laboratory technicians in Washington and Baltimore propose to form an association of laboratory technicians, which would have as its object the dissemination of technical knowledge along medical laboratory lines and the maintenance of a high standard and ideal among this body of workers. A precedent for such an organization has already been established in Great Britain in the

Pathological and Bacteriological Laboratory Assistants' Association, which has done a most valuable work during the thirteen years since its foundation. We are glad to notice that the American laboratory technicians have sought the advice and example of the Pathological and Bacteriological Laboratory Assistants' Association, an account of whose objects and proceedings is printed in Bulletin No. XI of the International Association of Medical Museums.

MEDICAL SOCIETY OF LONDON

THE programme for the first half of the 153rd session of the Medical Society of London has just been issued. The annual general meeting, on Monday, October 12th, at 8 p.m., will be followed by the presidential address. The subject of Sir Holburt Waring's address is "Osteopathy, chiropractic, and medicine," and it will be followed by a discussion. Clinical evenings will be held on October 26th and November 23rd, when cases and diagrams will be shown and discussed. On November 9th a discussion on "Obscure pyrexia in childhood" will be opened by Dr Robert Hutchison, followed by Dr Wilfred Pearson and Professor F. S. Langmead. Another discussion has been arranged for December 14th, when "The treatment of genito-urinary tuberculosis in the male" is to be introduced by Mr Cyril Nitch, followed by Mr Kenneth Waller and Dr Stephen Gloyne. The dates of Dr L. Fairclough Buzzard's Lettsomian Lectures on "The principles of treatment in relation to diseases of the nervous system" are February 15th and 24th and March 15th. The Annual Oration will be delivered in May by Sir Berkeley Moynihan, Bt. The syllabus of the second half of the session 1925-26 will be published early in January. The honorary secretaries are Mr J. E. H. Roberts, F.R.C.S., and Dr T. G. Chandler.

INFLUENZA

THE Registrar-General's returns suggest that influenza is again tending to become epidemic. The deaths in the great towns during the last three weeks have been 11, 26, and 41. The notifications of pneumonia have amounted to 417, 578, and 764. The numbers are not very great, but the upward movement is somewhat unusually early in the season. The distribution of cases of pneumonia suggests that it is in the north midland and northern parts of the country (including the north-west) that the epidemic will develop first. The returns for London do not show so regular a change, the deaths from influenza have been 1, 7, and 5 in the last three weeks, the notifications of pneumonitis 29, 68, and 79.

A CONFERENCE on the subject, "How the midwife can help in the reduction of maternal and infantile mortality," will be held at the Royal Society of Arts, John Street, Adelphi W.C.2 on Monday, November 9th, from 5 to 7 p.m. The chair will be taken by Sir Francis Champneys, Bt., M.D., chairman of the Central Midwives Board. The midwife's place in the maternity service will be discussed by Dr John S. Fairbairn, obstetric physician to St. Thomas's Hospital, the midwife in independent practice, by Miss E. M. Doubleday, of the Post-Certificate School, the midwife's work in rural areas by Dr F. E. Fremantle, M.P., and the midwife's work in large centres, by Sir John Robertson, M.O.H. Birmingham. A general discussion will follow.

THE Home Ambulance Service of the Joint Council of the Order of St. John and the British Red Cross Society (19 Berkeley Street, London, W.1) has issued a new edition of its list of ambulance stations, showing the address of each and the officer in charge. We recently (August 29th, p. 396) gave an account of the work at present carried on with so much success by the Home Ambulance Committee and described the means taken to keep the ambulances at all the stations in good working order.

Opening of the Winter Session.

POETRY AND PHYSIC*

BY

SIR HUMPHRY ROLLESTON, BART, A.C.B., M.D.,
HON. D.S.C. OXFORD, D.C.L. DURHAMREGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE,
PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

THE present is perhaps not an inappropriate time to consider the relations between poetry and physic, for less than a year ago (on October 23rd, 1924) we celebrated the 80th birthday of Dr Robert Bridges, Poet Laureate since 1913 and the only medical man among the eighteen holders of the office of Versificator Regis, dating from Edmund Spenser in 1591. The nearest approach to a medical laureate was Robert Southey, who for a time was a medical student.

Newcastle upon Tyne, too, has its medical poets, for Mark Akenside (1721-1770) composed his successful didactic poem, *Pleasures of the Imagination*, in this his native town before leaving for London and dropping the pursuit of the draggled muses—to quote the words of another medical poet, Oliver Goldsmith. Thomas Trotter (1760-1832), after a rather turbulent career as a surgeon in the Royal Navy (1779-1802), retired to Newcastle a disappointed man, and in 1829 published a volume, entitled *Sea-weeds, Poems Written on Various Occasions, Chiefly during a Naval Life*, and thus, as sometimes happens to medical men, returned to the poetic activity of early youth.

On grounds of ancient heredity poetry and physic should be closely allied, for Apollo, the god of poetry and culture, was the father of Aesculapius, the tutelary divinity of the healing art, and those who practised medicine were dignified as "the children of Apollo." In the time of the renaissance of learning medicine was one of the several branches of knowledge coming within the purview of a philosophic scholar, and these were the days of the scholar physicians, such as Linacre. The relations between literature and medicine form an interesting episode in the history of letters, but the connexion has of necessity become less intimate with the advance and increasing specialization of knowledge and technique. Even in the experience of those now living it seems to some that poetry, in spite of the volumes of *Georgian Verse*, has less appeal and is less read than in Victorian times.

Some years ago the idea struck me that it would be interesting to collect the works of medical men who were also poets for our profession provides ample opportunity for observing man and his manners, women and their ways, human nature and its nakedness, and the beginnings, ends, and tragedies of our fellows. Such a hobby is attractive for the light it throws on the personalities of the past and for the pictures of eminent physicians such as Sir Henry Hallford composing elegant Latin verse (*Vagae Medicae*, 1842) as he drove from one noble sick room to another, Sir Richard Blackmore, the opponent and victim of the wits, rolling out his eternal epics to the rumbling of his coach's wheels, and thus contrasting with the humbler practitioner, John Mason Good (1764-1827), translating Lucretius into blank verse as he trudged through the London streets to his poor patients, this literary task, conscientiously undertaken for his mental education occupied six years. But I had barely started when Dr C. L. Dana of New York kindly sent me the charming catalogue of his collection of poetical works written by medical men, which, covering a period of two thousand years and containing 157 names and 295 works, compelled admiring interest while defying competition.

The relations of medicine and literature have often been the subject of addresses and articles, and I would specially refer to Sir Edmund Gosse's brilliant Lloyd Roberts Lecture on

Personal relations between literature and medicine,† to which I am much indebted. In 1669 the distinguished Dutch anatomist Thomas Bartholinus published a small work of 149 pages *De Medicis Poetis*. Broeckx, in his *Dissertation sur la médecine poétique belge*, arranges fifty of his countrymen in alphabetical order, and Académie Chéreau gives in alphabetical

order no fewer than 479 names, but modestly says that Traut cannot put forward any competitors to the poet physicians who are mentioned in order, presumably of merit: Francesco Redi, Bellini, Blackmore, Haller, Alenside Grainger, Erasmus Darwin, Armstrong, Carth, and others. In his scholarly introduction Dan passes in review the medical poets from classical times, from Impedocles (B.C. 500) and the times when the Theriacal or Emetic for all poisons was a favourite subject for the verses of Alexander, Andromachus, and Macer Floridus, up to the present day.

Uses of Poetry

Defined as articulated music by John Dryden, poetry has to please what a great painter's masterpiece is to an ordinary photograph. It is eminently creative, medicine, though similarly constructive in its curative and older function, has as its highest aim the prevention of disease, and therefore, like the police, plays the rather negative part of eliminating the factors responsible for disorder and destruction. But in their different ways scientific medicine and poetry both aim at the attainment and perpetuation of the good, the beautiful, and the true.

Though it is not always recognized, poetry has a most practical bearing on our work a day world by increasing the joy of existence. With their realistic and idealist sides medicine and poetry are complementary, and certainly poetry provides a relief from the ugliness and drabness of life. No doubt the idealism of the poet's eye "in a fine frenzy rolling" so remote from the sordid material details of fleshly infirmity, would appear to set an insuperable gulf between him and the physician. But each of those concerned with these contrasted aspects of life may gain by adopting colouring derived from the other.

Medical men, however, are probably more likely to gain by the culture and wide vistas opened by poetry and letters than are poets by a scientific or medical training. In his *Essays in Criticism* Matthew Arnold indeed insisted that without poetry science would be incomplete. Poetry implies spontaneity and imagination which should not degenerate into poetic licence, and imagination, or the creative faculty, is a form of divination of the greatest importance in medicine. Indeed, according to Sir Clifford Allbutt, the responsibility of a university is confined to ensuring a certain development of mind and imagination in its graduates. Imagination is a necessary stimulus to really good work, especially in original research, it is as essential as is the cold logical sense of proportion which controls within proper bounds the investigations thus inspired, for it is the most fruitful initiative to lines of pains taking and laborious investigation. That familiarity with good poetry should improve a medical man's literary style is so obvious that one example only will be cited, and that from holy writ. St Luke, the beloved physician, was, as Miss Melan Stawell shows, a Roman and not a Greek, and modelled his style in the Gospel and Acts of the Apostles on Virgil.

Like music, poetry of course has an effect on the mind, and the finer forms exert a powerful influence for good. Robert Graves says: "A well chosen anthology is a complete dispensary of medicine for the more common mental disorders, and may be used as much for prevention as cure." There can be little doubt of the value of poetry as a relief to the mental fatigue caused by the monotony and squalor of life such as we often see it, but it is possible that Robert Lynd is right in reproaching us for neglecting its psychotherapeutic uses. But he says that we are more accustomed to advising people to eat lettuce than to read poetry, and that in view of our silence Graves is justified in advocating the medical applications of poetry. In a passage that reads like a page of Aristotle seen through the spectacles of Dr Freud,† For Graves suggests that as poetry is the transformation into dream symbolism of some disturbing emotional crisis in the poet's mind, it is able to help other men similarly affected by supplying an allegorical solution of the trouble. Not only may reading poetry soothe the jangled nerves of a jaded labourer and provide an antidote and an antidote to the mental hyperchlorhydria born of the too material and stereotyped formulae of medicine, but active composition of verse is a means of

* Introductory Address (delivered) at the University of Durham College of Medicine, Newcastle upon Tyne, October 6th, 1925.
† *British Medical Journal*, October 2nd, 1925, 1, 52.

relieving the overburdened mind by providing a safe outlet for emotional excitement.

The valuable property of "clinical instinct," which, although sometimes ridiculed as the assumed armour and decoration of the ignoramus or the quack, has a certain resemblance to the poetic faculty, and, moreover, is a real asset in practice. Clinical instinct is the power of arriving without a conscious logical process at a definite conclusion, and is often possessed to a high degree by old nurses who know, but cannot give their reasons, whether a patient is going to recover or die, and by practitioners of long experience who similarly cannot explain the steps by which they reach a diagnosis and prognosis. It may be assumed that they unwittingly draw on a buried experience which, without their conscious remembrance, recognizes in the patient signs presented by one in the long past. In diagnosis, therefore, there are the two processes—the consciously logical, and the rarer, but not necessarily less correct, the unconscious. In the writing of poetry there are also these two methods—the conscious effort and the impulsive pouring out pell mell of verse, the meaning of which, though quite clear to others, may not at the time be obvious to the writer.

Poetry as a Means of Communicating Knowledge

The prolific multiplication of books by printing has rendered the transmission of knowledge so easy that it has led to the conviction that prose is the only proper method of conveying technical knowledge, but, of course, it was not ever thus. In early times medical, like other lore, was largely handed down in the form, convenient for memory, of verse. In the past the famous *Regimen Sanitatis* of Salerno (? 1100 A.D. and an early printed book in 1480) was the most popular poem in medical literature, up to 1835 there were 119 editions of the Latin text, 33 German translations, 14 French 9 English, 9 Italian. As recently as 1920 an edition of Sir John Harrington's English version was published. It was much in request as a handbook of domestic medicine, and, as was so frequent in the days before printed books, became much altered in the course of many copyings, successive scribes adding at their own discretion or indiscretion. Thus the early copies contained about 360 lines, and the later ones over 1,000. Johann Joachim's *Parno us Medicinalis* (1663), written in the style of the *Regimen*, was, according to Dana, notable as the first systematic exploitation of opotherapy and details the applications of twenty-four substances in man's body useful in medicine. Next in popular importance to the *Regimen* Sir William Osler placed Girolamo Fracastoro's *Syphilis et Morbus Gallicus* (1530), which gave us the name of a disease, the etiological importance of which it is even now difficult to estimate. David Hume's *Scott's chief Latin medical poet* being the author of two volumes *De hominis præcatione anatomie morbis internis* (1596), another Scot John Armstrong (1709-1772), produced *The Famous Art of Prescribing Health* (1744), a didactic poem in four books, which, with its personal appeal, had a great vogue.

Can a Doctor be a Poet?

Ever at any rate in the recent past, have at the same time been equally distinguished as medical men and writers of poetry. Probably the best instances are the two Americans, Oliver Wendell Holmes (1809-1894), professor of anatomy for forty-four years, and S. Weir Mitchell (1829-1914) the neurologist of Philadelphia. This association, however, has been so rare that it has even been asked, "Can a doctor be a poet?" and with a wider application. Is there any inherent incompatibility between the lancet and the lyre? Thomas Denman (1733-1815), the obstetrician in a letter to comfort his former pupil the famous old Bath physician Caleb Hillier Parr for the tardy advent of patients during his early years of practice, touched on the perennial problem why one medical man succeeds while another fails remarking "What is very hard, and I know two or three instances of it is that a man shall be esteemed as a friend acknowledged to be a man of parts, but none of his friends thinks of employing him in his profession. Thus I can hardly explain him by the old saying 'He is too good a poet to be a good physician.' This was in the very early years of the nineteenth century more than a century after the appearance of Samuel Butler's *Dicynary* (1699), a medico-political satire and picture of the famous quarrel between the College of Physicians and the Apothecaries, which Sir Edmund Cosseville, then a fully qualified *comp de grace*

to the popular belief that the pursuit of poetry and of medical practice were incompatible.

It has long been a widespread conviction which the ever increasing extension of knowledge and the resulting specialism would tend to strengthen, that a man cannot be first rate in more than one line of work. It is true that some men are so gifted that whatever profession they adopt they will make their mark at or near the top, Goethe and Albrecht von Haller in the past were examples of pre-eminence in poetry and medical science respectively, and efficiency in their second subject. Benjamin Ward Richardson believed that if John Keats had once tasted the true spirit of medicine he would have become one of her greatest sons—in addition, perchance, to the some eight or ten of the men of all time whom medicine claims as her own, her poets of nature.

In the light of experience and in obedience to popular prejudice against serving two masters or mistresses, some medical men have concealed their poetic powers and productions, or have put them aside in a napkin during their active professional life. To publish anonymously and to await the verdict before declaring the responsibility is not peculiar to any profession, and ours is no exception. There has been some discussion whether the unauthorized and anonymous editions of Sir Thomas Browne's *Religio Medici*, which contain a number of poetic fragments in the text, appeared entirely without his knowledge, but Geoffrey Keynes, in his fine bibliography of Sir Thomas Browne, scouts any such sharp practice on his hero's part, though this is perhaps rather a hard saving for what, after all, seems a harmless experiment. From internal evidence Chereau ascribes thirty-two unsigned poems to medical men among his collection of French physician-poets. Pseudonyms also have naturally been employed.

Marl Alenside (1721-1770) brought out the *Pleasures of the Imagination* in his twenty-third year, and then, becoming a haughty physician to St. Thomas's and Christ's Hospitals, and Gonistomian and Croonian Lecturer at the Royal College of Physicians, remained to all intents poetically dumb until the year of his death. Possibly he was influenced by the example of his senior at the College, Sir Richard Blackmore (1653-1729), Physician in Ordinary to William III and Queen Anne who persisted in the practice of physic and the publication of epics, with the result that he became the butt of the wits, whom, it should be remembered, he had in the first instance attacked in a *Satyr against Wit* (1700).

Garth and John Arbuthnot (1657-1735), the only hegetter of the character of John Bull, were both court physicians and accepted equally by the wits and by the medical world of what has been called the Augustan Age in England. That they had personal charm is well known and this is perhaps the reason why Blackmore, their apparently heavy colleague at the College and the court, had such a different reception. At any rate, Garth and Arbuthnot's success proves that in spite of popular prejudice it was not impossible to be accepted as a physician and a poet at the same time at least in those days. Even now with all our intensive specialization, there are not wanting men of world-wide reputation who can write fine verse. Henry Heids *Destroyers* and Donald Ross's poems are instances that at once spring to mind but it must be admitted that their services to medical science outshine even their poetical works. Sir Donald MacAlister's *Echoes* (1913) are an amazing *tour de force*, for he translates Roman into English, German into English and Scots verse and vice versa Russian and modern Greek into English and old Scots with the greatest skill and apparent ease.

Practitioners of Poet Medicine and Ver

It has been claimed for medicine by one of ourselves (Mitchell Branks) that it stands foremost among the professions in the number of men distinguished in literature who at least began life in our ranks. A long list might easily be compiled but it will be sufficient to give a few examples of those who have taken up medicine for a shorter or longer time and have, as one sage or another given their adhesion to the muse of song. Some have been poets who touched medicine, others practitioners who as a by-product or hobby, threw off verse, and some such as Georges Clemenceau in *Le Grand Pan* (1895), have preferred to write poetry in the form of prose. Some were transient students only and never qualified, S. T. Coleridge when less than 15 years of age, was seized with a passion for medicine and read many authorities, learning

Blancard's *Latin Medical Dictionary* almost by heart. Southey also entered on the physic line, but not for long. Francis Thompson (1859-1907), poet, author of *The Hound of Heaven*, and mystic, spent eight years at Owens College, Manchester, but as a medical student he was a misfit.

John Keats, as is well known, qualified in July, 1816, at the Apothecaries Hall, but this marked the close of his life's medical chapter. George Crabbe (1754-1832), according to Byron, Nature's sternest punter, yet the best, after a brief experience of poor practice took orders, and only ever criticised his medical knowledge on the bodies attached to the souls under his care. Medicine may be said to have refused the overtures of Goldsmith, the source of whose medical qualification has been a vexed problem of historical research, and Tobias Smollett, the author of odes as well as his more famous novels, intermittently attempted, but never really succeeded in, practice. Schiller gave up his post as a surgeon in the army as soon as he could.

Among those who continued to practise and publish their metrical products were Henry Vaughan (1622-1695), his *Retreat* appears to have stimulated Wordsworth to the ode *Intimation of Immortality*, and his poems were pervaded with an atmosphere of mystic rapture, he evidently was no commonplace person. James Granger (1721-1766) was successful in so far as his *Ode to Solitude* was applauded by Johnson, and he gained at least sensational attention for *The Sugar Cane*, the remarkable anticlimax in which, 'Sav, shall I sing of rats?' evoked a rebuke from the great lexicographer and laughter from the privileged audience to whom it was read. He carried on his professional and poetic activities concurrently, but, though able, he did not make medical practice lucrative. In the intervals of his more important work Edward Jenner (1749-1823) wrote occasionally in verse, such as the *Address to a Robin*. John Ferriar (1761-1815) of Manchester, advocate of the idea that anyone could become a genius if sufficiently industrious, was the author of a poem *Bibliomania* recounting the joys of book collectors, and became prominent for his attack on Sterne, whom he accused of plagiarisms, a failing which others in turn ascribed to the critic. He was active as a physician to the Manchester Infirmary until his death. W. H. Drummond (1854-1907), who has been called "the Poet Laureate of British America," struck out a new line as the interpreter of the French Canadian life and thought in *The Voyageur*, *The Habitant*, and other poems. He was of Montreal, and so was John McCrae (1872-1918), whose untimely death in the war removed a well-known pathologist, a physician of great promise, and the critical author of a number of poems, the best known of which is the exquisite rondeau *In Flanders Fields*. W. S. Thayer of Baltimore, another fastidious censor of his own creations, has often written but seldom broadcasted his verse.

Another group are those medical men whose poetic bent is not allowed to slumber before men until they are on the way to retirement when more leisure and freedom from any anxiety that obvious hobbies may damage their professional prospects permit the products and remains of youthful facility in verse to blossom forth. Weir Mitchell was a case in point, except for some unsigned verses in 1857, he published nothing for popular consumption until over 50 years of age. In spite of Sainte Beuve's dictum that in most men the poet dies young while the rest of the man lives on, it is therefore probable that poetic activity may be latent and be born again in more mature years, but whether the latest fruit is always the ripest is doubtful. Erasmus Darwin (1731-1802) was the author in his fiftieth year of *The Botanic Garden*, a poem in two parts, the *Economy of Vegetation*, and *The Loves of the Plants*. There is a special interest about him and his speculations on evolution in connexion with their possible influence on his grandson Charles Darwin, who entered, but soon abandoned, the study of medicine. Thomas Gordon Haake (1809-1895), a Victorian poet made a much cleaner cut between his professional and poetic life than did Erasmus Darwin, for he left physic with the definite intention of cultivating the muses about the age of 50, after which nearly all his poems were written.

It is seldom that one who starts as a poet takes up medicine comparatively late in life, the following examples show an infinite variety of interests. Thomas Lodge (1558-1625) had an adventurous career: the son of a Lord Mayor of London, he went to the Bar, travelled much, was a soldier and sailor too, not to say a freebooter, in the Spanish Main and the

Brazils, and was the persistent parent of plays, pamphlets, and poems. After 1595, a year of great literary activity marked by the appearance of four books, he went in for medicine and, taking the degree of Doctor of Medicine at Avignon in 1600 and D.M. of Oxford in 1602, practised at first in Warwick Lane. Familiarity with the pen crippled him, in 1603, to dedicate to the Lord Mayor and Corporation a treatise on the plague then raging in London. Together with Matthew Gwinne and Raphael Thorus, both poets, the great William Harvey, and some others, he was, on May 11th, 1604, examined at the Royal College of Physicians, Lodge failed on that occasion, but was successful in 1609. Martin Llewellyn (1616-1682) also plied many parts: a scholar and poet, cavalier, until he was 32, when he was ejected from Oxford for his Royalist activity, then applying his genius to medicine he became a Fellow of the Royal College of Physicians of London, but with the return of the Stuarts he was made physician to Charles II and Principal of St Mary's Hall, Oxford, after four years he moved to Great Wymondley, where he practised and eventually became mayor, he wrote poems, published at intervals from 1646 to 1672. T. L. Beddoes published *The Bride's Tragedy* when 19 years of age, wrote dramas, became involved in political intrigues in Germany, and remaining abroad for the rest of his life decided, in 1825, to abandon literature as a profession in favour of medicine. He attained merit as a physiologist, took his doctorate in Zurich in 1835, was nominated as a professor but not appointed for political reasons, and did some practice. During twenty years of his medical life he was writing and polishing *Death's Jest Book or the Fool's Tragedy*, published in 1850 after his death.

A few born poets adopt medicine, and failing therein allow their true bent to come out, as in the case of Oliver Goldsmith. It must be exceptional, if not unique, for a well established poet to be summarily made M.D., even by the Archbishop of Canterbury—who still returns, but never uses, this power. Abraham Cowley (1618-1667), a scholar of Trinity College, Cambridge, wrote in 1639 an elegy on the death of his friend William Harvey, not to be confused with the discoverer (1578-1657) of the circulation, whom as Warden of Merton and a co-Royalist he very probably met at Oxford after his expulsion from Cambridge in 1643. It was at Oxford, on December 2nd, 1657, that Abraham Cowley was made D.M. by edict of the Government in order (so his biographer, Spurr, considers) to serve as a blind for his activities in the Royalist cause. Cowley never published any strictly medical work, and there is no evidence that he was specially interested in clinics.

Is any one branch of the medical profession more favourably placed and prolific in verse than another? From then up bringing and associations it would naturally be anticipated that the followers of pure physic would be more productive than the wielders of the knife: this is probably true, but perhaps enough has been said about those concerned with internal medicine. Some distinguished surgeons have been poets, or at least have ventured into verse. Richard von Volkmann wrote under the name of Richard Leander. Paul Broca was a poet (employing the anagram Bp Lacour for his pseudonym) as well as a surgeon and an anthropologist. Sir William Blizard, who was surgeon to the London Hospital for fifty-three years and operated there in his eightieth year, wrote an ode for the opening of its Medical School in 1785, which was set to music by Samuel Arnold, but drew from Sir Norman Moore the remark that had he been longer contemporary with Pope it would have certainly secured him a place in the Dunciad. Another President of the Royal College of Surgeons, the late Sir Rickman Godlee, wrote poems. Sir D. Arcy Power, ever ready to share his historical lore with others, has shown me some of his treasures of the sixteenth century poet surgeons, John Halle, Thomas Gale, Thomas Vicary, and John Read, while engaged in trying to raise the status of surgery in this country, found time to diversify their surgical works and to produce occasional poems. The poetic habit of these Elizabethan surgeons was a fashion which faded away, but no doubt will be revived in due season.

Of the various specialties one of the most select is that of the anaesthetist, and I have personal knowledge of one who, possibly inspired by their environment and provided with time for meditation while their surgeons are busy, have cultivated verse. Laryngology, now such an energetic and successful specialty, has, as indeed is only right, contributed

its quota of song. Men in general practice form the bull of the profession, and though not in the limelight, have done then share in keeping up the scholarly and poetical reputation of their profession. Some have been mentioned already, and of living men it is perhaps invidious to speak, for there are so many, and it is so difficult to keep in touch with all current poetry. Moreover, many hide their talent as if it were a secret vice.

What, then, is the conclusion of the whole matter as shown by experience? The reading of poetry is a help, comfort, and means of culture in our hours of ease and even of disease, and as a hobby the writing of verse is a happy issue for our emotions, for there is no greater pleasure than creating something. Surely these are enough to establish the advantages of the cultivation of poetry? More ambitious aims are hardly likely to tempt us, for it is fairly obvious that, as medicine and poetry are both jealous mistresses, a busy doctor can hardly hope ever to be a Tennyson or a Swinburne.

FIFTY FIVE YEARS OF PROGRESS IN SURGERY

BY

SIR ARTHUR MAYO ROBSON, KBE, CB, CVO,
DSc FRCS

EMERITUS PROFESSOR OF SURGERY IN LEEDS UNIVERSITY, AND CONSULTING
SURGEON TO THE LEEDS GENERAL INFIRMARY

I FEEL it a great honour to have been asked to give the opening address of the Medical Department of the Leeds University as to-day is the fifty fifth anniversary of my entering as a student, and, with short intervals for post graduate study at home and abroad, it was my privilege to be attached, in one capacity or another, to my Alma Mater for over thirty years before making London my centre. It is therefore not an idle boast to lay claim to some knowledge, not only of the evolution of the Medical Department, but of the University itself, of which I am proud to be one of its early emeritus professors and to have been considered worthy of the distinction of receiving *honoris causa* the degree of Doctor of Science. Not the least among the great mercies vouchsafed to me is the privilege in my eighth decade of being able to accept your kind invitation to come and greet those who remain, alas too few, of my old friends, and to make the acquaintance of those new colleagues who are still carrying on the work so well that the reputation of this great teaching centre is increasing from year to year.

The Dean of the Faculty has, in his kind letter of invitation practically fixed my subject for me in stating: "There are now very few persons who can, from their actual knowledge, compare and contrast the nineteenth and twentieth centuries or even assess the causes and influences of the changes which have occurred." But when I began to consider how impossible it would be, in the course of an hour, to give any details of even the greatest discoveries that have been made during my lifetime, or even to describe all the changes that have transformed our own profession, I felt that it would be necessary to limit my remarks to my own sphere of work, which in itself is enough to mark this period as the most wonderful in the history of the world.

On looking back and reviewing the changes that have taken place in the art and science of medicine and surgery since the days that were to unlock the paths to progress were discovered, I am lost in wonder at the perseverance and tenacity, the skill and ability of those great men, whose conscientious labour accomplished so much in the absence of any accurate knowledge of the causes that led to want of success and were the prelude to successes that some of them lived to see and participate in. Among the many distinguished men of our profession of this and other countries, whose names will be ever remembered, I come that we of the Leeds School should especially bear in mind the Heys, the Tenles, Clifford Albutt, Wheelhouse, Jessop and McGill, my teachers and later my colleagues and friends. Although alas! they have passed away, their spirit continues with us to stimulate us to higher endeavours in continuing the work so well begun.

Address (abridged) delivered at the opening of the Medical Department of the Leeds Infirmary on October 1st 1925.

I had the good fortune to begin my life's work in 1870, when there were great advantages in writing and talking, put in the old order of things and being able at once to appreciate and participate in the reformation that came within the next few years of seeing the birth and growth of the science of bacteriology, the key that unlocked the way to the knowledge of the cause of so many diseases, of taking part in the infancy, the adolescence, and the sturdy manhood of its brilliant offspring antiseptic and aseptic surgery, and of having, the honour of making a personal acquaintance with, and of being an ardent disciple of, those two great masters—Lister and Lister. To those of my audience who are entering on their medical studies to-day, and to any other students who have not read them, let me recommend two books which will not only give you the greatest pleasure to read and carefully study, but which will stimulate you in your careers and afford you great examples to live up to. They are (1) *The Life of Pasteur*, by his son-in-law, Rene Vallery Radot, which I read when first published in the original, but which I have read a second time, with equal interest, in a very good translation by Mrs R L Devonshire, with an excellent introduction by my late distinguished friend Professor Osler. (2) *The Life of Lord Lister*, by his nephew, the late Sir Richard Godlee for some time a colleague of mine on the Council of the Royal College of Surgeons, and later President, who was himself a distinguished surgeon.

In the early seventies, it was possible to see hospitals ravaged with hospital gangrene, septicaemia, and pyaemia, when any operation, however simple, might, and frequently did, assume complications of the most serious import, often ending in death. For instance, I actually saw death follow the simple tapping of a hydrocele by an eminent surgeon. Secondary haemorrhage was of frequent occurrence, and it was usually considered advisable to have tourniquets at hand or even round limbs ready for the attendants to tighten up when the silk ligatures were due to separate. Ordinary compound fractures often ended in loss of life or limb or took weeks or months to heal, and not infrequently ended in shortened or crippled limbs. Lividities, pyaemia, septicaemia, and tetanus were never long absent from surgical wards. Erysipelas was explained by change of weather, tetanus by nerve irritation, tubercle by dirtiness, and rapid deaths from septicaemia by shock. Abdominal diseases were treated expectantly, practically always, and if we refer to the hospital reports of the very few cases operated on in the large London and provincial hospitals we shall see that it was a wise provision that such cases were handed over to the physicians by universal consent. They considered the adoption of palliative measures and the making of a diagnosis quite adequate, until Nature relieved the victims and enabled a confirmation or otherwise of their diagnoses to be made on the *post mortem* table.

Viewed from our present standpoint and our knowledge of surgical cleanliness, can we wonder at the state of affairs in the seventies, and even to the early eighties, when little care was spent on cleansing the hands and nails of surgeons, assistants, and nurses, and none in purifying the skin of the patient when perfunctory washing was supposed to be sufficient for the cleansing of instruments and sponges when silk ligatures, without any preparation, were taken straight from the storeroom cabinet, and often handed to the surgeon by the theatre porter who might at the same time be *post mortem* room attendant? Dressings were used as they were delivered from the makers. Clean and septic cases were operated on indiscriminately in the same theatre, and nursed and dressed in adjoining beds. The surgeons wore long special operating coats, made of firm cloth which buttoned up to the neck like a military garment in order to protect their own clothes and not as now sterilized garments, changed for each operation to guard the patient from contamination.

Entering on my studies in 1870 my qualification to practice was obtained in 1874 and the FRCS in 1878. Although engaged in general practice by force of circumstance I received the appointment of demonstrator of anatomy in the Medical School later followed by a lecturehip. A regular attendance in the wards of the infirmary and at the weekly consultations on rare or difficult cases, held in the operating theatre, at which the whole of the surgical staff attended diligently and a constant study of everything upper aiming to surgery, enabled me to keep abreast of all surgical advances.

and to attend, as occasion offered, post graduate work at other clinics

Soon after receiving my qualification in 1874 I was asked by a medical man if I would go to Glasgow to be present at an operation—amputation of the thigh for venio gangrene—about to be performed on a relation of his, by a general practitioner. The doctors arrived with two large stone bottles of whisky, which was poured into several washhand basins. Into one were placed the instruments and silk ligatures into another sponges, and into another dressings, while another served for soaking the hands of the surgeon and washing the patient's thigh at the line of amputation. The limb was amputated expeditiously and well, the vessels were ligatured with fine silk, the ligatures being cut short, the face of the stump was well sponged with pure whisky and the flaps were sutured, the stump being closed without drainage. Fine towels wet with whisky, were placed over the stump so as to make a complete and well padded dressing, which was then handaged on and supported by a short splint. The patient made a complete recovery, and the wound healed by first intention.

Thus I saw my first perfect aseptic—or should it be called antiseptic?—major operation, which made a great impression on my mind and served me as an example for many subsequent successes. I have often thought with gratitude of that able surgeon and his great skill. During all this time I had the opportunity of doing a fair amount of surgical work, such as occurs in general practice, and of obtaining results by antiseptic methods, which gave me as much pleasure as it gave comfort and safety to my patients, whose gratitude was an ample reward.

The year 1870 was the memorable and tragic year of the Franco German war, which was not only accompanied by frightful losses on the field, but by even more terrible losses through disease and of the wounded, who were dying in thousands, whether attended to or not for of those operated upon by far the greater number died of wound complications. It was only at the end of the war that there occurred to Alphonse Guérin the thought that "The cause of gunshot infections may perhaps be due to the germs or ferments discovered by Pasteur to exist in the air." It occurred to him to filter the air by means of cotton wool, and he also washed the wounds with carbolic solution or with camphorated alcohol before applying the wool. This was at the St. Louis Hospital, from March to June, 1871, in operating on the wounded of the Commune, and it was thought wonderful that out of 34 patients thus treated 19 survived. In 1873 Guérin, now a surgeon at the Hotel Dieu, asked Pasteur to come and see his dressings. A little later I had the opportunity of visiting that famous hospital and of seeing the voluminous dressings on the numerous amputations, practically the only operations then performed, and of witnessing some successes and many failures, for when the dressings were removed there were far too many sloughing flaps, with spreading gangrene, accompanied by collections of offensive pus, and even maggots, in the putrid mass. There are, of course, greater dangers than the germs from the air—those conveyed by hands, dressings, sponges, and instruments, and if precautions are not taken against them only very imperfect success can follow. It was not the art of surgery but the science that was at fault, for there were brilliant operators in those days, when rapidly was a legacy left by the pre-anaesthetic times, as witnessed by the amputation of limbs in periods of time marked by seconds.

In Lister's operations, instruments, sponges, and other articles used were all taken straight out of strong carbolic solution, and the same precautions were used for the hands of the surgeon and his assistants, and a special dressing of carbolic putty, or carbolic resin gauze, was placed immediately over the wound, under the outer dressings.

Although between 1867 and 1869, 34 out of 40 amputations had survived in Lister's wards, his isolated voice was not attended to, and not even his celebrated lecture in 1870 on

The utility of antiseptics applied to surgical practice received the attention it demanded. It is sad to think of the thousands of young men who perished in the ambulances and hospitals of France in 1870 and 1871, who might have been saved by Lister's method. But the heads of the profession in France took no interest in the rumours of the success being attained by antiseptic methods and even in his own country Lister's method was violently criticized and turned down. This opposition continued year after year to my knowledge, and even pursued Lister when he was appointed surgeon to King's College, London where some of his colleagues on the staff were his

bitterest opponents. As an ardent disciple, I had the advantage of following his work, as to the value of which I had had no doubt from the time I began my surgical studies and became acquainted with the doctrines of Pasteur and Lister.

Even in the early eighties, when I had the honour to be appointed honorary surgeon to the Leeds General Infirmary, my distinguished predecessor handed me with pride and with some ceremony his operating coat, which he was still using, and which he had used for years. It was covered with innumerable spots of old clotted blood. I began my work by wearing washable garments frequently changed, and when requesting the same for my assistants and nurses the question of laundry expenses was raised. At a later stage, when initiating the wearing at all my operations of boiled rubber gloves, on the advent of aseptic in place of antiseptic surgery, the complaint of extravagance was even more strongly urged, and was only settled, as time wore on, by the results, which compelled their general adoption.

During the time that operations were limited in number it was always possible to obtain the services of one of the qualified residents as anaesthetist, but when, as the result of greater success, operative work increased, students without any special training were allowed to administer anaesthetics. This, as will be readily grasped, frequently caused great anxiety to the surgeon and some danger to the patient. I therefore brought up the subject at a faculty meeting, and proposed that special anaesthetists should be appointed. Two specious arguments were raised against my proposal: first, that the cost of skilled and qualified anaesthetists would be a serious expense, and secondly, that students could only learn by personal experience, the result being that my resolution had not a single supporter, and was not even seconded. Considering the matter of such great importance, my only alternative was to ask for a special meeting of the whole weekly board, which included not only the faculty but the lay members of the board. After a full explanation of my views as to our responsibilities and the dangers to life, were the present system continued, it was a great relief to me when my resolution was carried without a dissentient vote in a very full meeting, and three anaesthetists were appointed without any delay. There are now no fewer than nine highly qualified anaesthetists on the staff, which of itself shows that the initial struggle was very necessary.

A comparison between the reports of 1870 and 1925 of the Leeds General Infirmary will perhaps illustrate better than any other plan what wonderful progress has taken place in fifty-five years, and how many new discoveries have been brought into our service in diagnosis and treatment during that interval of time.

Abdominal Surgery

On taking up my appointment on the staff of the infirmary, abdominal surgery was practically confined to ovariectomy, of which the mortality was 25.6 per cent.

Before beginning my work I thought it would be helpful to visit various clinics, from which I returned more than ever impressed with the importance of strict cleanliness, as shown by the work of the late Thomas Keith in Edinburgh, to whom I owe a great debt of gratitude for his help and encouragement. At first, using antiseptics as advocated by Lister (which, although they kill the germs, at the same time damage the tissues), I became more and more impressed with the value of asepsis, or absolute cleanliness, which avoids the introduction into wounds of any germs, thus rendering the use of strong poisons, such as carbolic acid, unnecessary. Metchnikoff's researches, which showed the phagocytic power of the white

corpuscles in wounds, enabled the presence of the very few organisms in the air to be ignored, if every crevice was taken by the surgeon not to introduce any by hands, instruments, sponges, or dressings.

In 1889 I published a list of all my abdominal operations from the time of beginning my work in the infirmary. This paper was read at the meeting of the British Medical Association in Leeds in August, 1889.¹

There were 61 ovariectomies with only two deaths, equal to 3.2 per cent. 12 cases of cholecystotomy for gall stones and 1 of cholecystenterostomy without a death, 28 cases of radical cure of hernia, 6 cases of pelvic abscess, 5 cases of tuberculous peritonitis, and 2 cases of hydatid of liver all without a death. 30 cases of strangulated hernia with 5 deaths, all from gangrene or rupture of the intestine but none from wound complications. 14 cases of operation for myoma of uterus including hysterectomy, with 5 deaths and 15 operations for malignant disease too extensive for removal and cases of general peritonitis from ruptured viscera with 9 deaths.

This list serves to illustrate the great advances that had been made in abdominal surgery up to 1889.

On June 21st, 1884, I performed my first operation for gall stones, and began to devote special attention to diseases of the gall bladder and bile ducts. After an experience of nearly 200 operations for gall stones, in the absence of malignant disease, profound jaundice, or infective cholangitis, with the loss of only a single patient, and even if the complications above mentioned be included, with a mortality of only 2.7 per cent, I decided to give my experience in book form, under the title of *Diseases of the Gall Bladder and Bile Duct* including gall stones, which was published in June, 1897. As showing the extension of this branch of surgery there were no fewer than 205 operations on the gall bladder and ducts performed in the infirmary last year, as given by the report for 1925.

The surgery of the stomach, pylorus, and duodenum next formed a very interesting and new field of work, in a class of cases treated before the reformation of surgery entirely by the physician, with only moderate and usually temporary relief. The success of surgical treatment, which enabled the stomach to be accurately examined in the living subject, added enormously to our knowledge of the pathology, and enabled us to put in practice a number of new operations, or more efficient modifications of older ones. After an experience of over 200 gastric operations, I was again elected Hunterian Professor at the Royal College of Surgeons in 1900, and took as my subject for the lectures *Diseases of the Stomach and their Surgical Treatment*. As no work on gastric surgery had been published and as much new and original material had accumulated for the purpose, I decided to write a work having the same title as the Hunterian Lectures, on which in fact it was based. I was fortunate in securing the help and collaboration of my colleague and former house surgeon, Mr Berkeley Moynihan, now our distinguished Professor of Surgery, St. Berkeley Moynihan, Bt., whose brilliant career has been a source of great pride to us all, and to me especially, since we were intimately associated when he was appointed assistant surgeon to the infirmary. Our first edition was published in 1901 and a second edition in June, 1904, when we were able to report an experience of 218 posterior gastroenterostomies in simple diseases of the stomach, with a mortality of 3.2 per cent, a great contrast with the year 1885, when the mortality from all sources was 65.71 per cent, whereas in 1890 it was 47 per cent and in 1900 35.4 per cent. As showing the growing importance of surgical treatment in diseases of the stomach and duodenum there were no fewer than 334 gastric operations performed in the infirmary in 1924, whereas only 2 were performed in 1884, both of which ended fatally.

My work on the gall bladder and bile ducts frequently compelled me to have to manipulate and carefully examine the pancreas, an organ which the surgeon (with the few exceptions of obvious cystic tumours or acute pancreatitis) had had little experience in. This new method of learning pathology from the living subject led me to recognize the frequency of chronic pancreatitis both as a concomitant of gall stones and as a separate and distinct disease, the cause being the invasion of the ducts and the infection of the gland by the colon bacillus. This led to the suspicion that many cases of obstructive jaundice hitherto diagnosed as cancer of the head of the pancreas which ended fatally, were not cancer but cirrhosis of

the head of the pancreas, a sequel of chronic pancreatitis compressing the common bile duct, which in 75 per cent of cases is completely enclosed by pancreatic tissue. This at once led me to see that by draining the gall bladder, or, better still, by short circuiting it into the duodenum, an operation known as cholecystenterostomy, another route for the bile would be formed and the jaundice would be cured. My first operation of cholecystenterostomy, and the first in England, was successfully performed in the infirmary in March, 1889, and the patient was seen quite well nine years later. A small decalcified bone hollow which, in various sizes, I had invented for intestinal anastomosis, was employed, though in later cases I used simple sutures with equal success.

The successful results of operation in several cases of deep jaundice associated with distended gall bladder confirmed my suspicion of chronic pancreatitis being the cause, but it was not until April 1st, 1892, that the opportunity of verifying the pathology occurred. Other observations in the pathology of the living led to an explanation of the apparent cure of a number of cases of diabetes by the removal of gall stones from the common duct, where they had produced irritation of the pancreas and interstitial pancreatitis, leading to interference with the glycogenic function of the islands of Langerhans in the substance of the pancreas, which function the researches of Koite, Oser, and Opie had previously discovered. The recent and remarkable discovery of insulin shows the value of the elaborate researches on the islands of Langerhans that were made by Körte, Oser, and Opie so many years ago.

After the accumulation of considerable experience in operations on the pancreas, I had the honour in 1904 of being appointed for the third time Hunterian Professor at the Royal College of Surgeons, taking as the subject of my lectures "The pathology and surgery of certain diseases of the pancreas." These were subsequently published, along with numerous additions, in a work entitled *Diseases of the Pancreas and their Surgical Treatment*, in which I again had the collaboration of my colleague Mr Berkeley Moynihan. During the whole time of my work on the pancreas I had had the valuable help, in various chemical and pathological questions constantly arising, of my friend Dr P. J. Cammidge in 1907 we published a work together, dealing largely with the pathology of the pancreas.

I must apologize for occupying so much time with my personal experiences in the progress of the surgery of the gall bladder and bile ducts, of the stomach, pylorus, and duodenum, and of the pancreas—subjects that I have been so much interested in. They are, however, only part of the advances that have been made in abdominal surgery in our time. Witness the operation for appendicitis which in my early professional career was the cause of death in many cases chronicled acute peritonitis or typhilitis, and in which the time cause was not recognized even on the *post mortem* table. My first of many hundred operations was on June 8th, 1891, and to mark the progress and success of surgical treatment it is only necessary to refer to the infirmary reports for 1885 and 1925. In the former appendicitis is not even mentioned, whereas in the latter 788 operations are recorded, with a mortality of only 3 per cent. Of intestinal surgery there was mentioned only one operation in 1870 whereas in 1925 there were 180. Of renal and ureteral surgery there is no recorded case in 1870, but 85 operations are reported in 1925. Of splenic surgery and hepatic surgery there is no mention in 1870 but 6 of the former and 9 of the latter in 1925. In extrauterine gestation, a rapidly fatal disease operation was unknown before Lawson Tait's first case in 1883 followed by many others. In 1893, in my valedictory address at the termination of my office as president of the London Gynaecological Society, I reported 23 operations with one death from pulmonary embolism. These statistics prove the advances between 1870 and 1925.

Brain Surgery

In 1874, when attending a course of lectures on mental diseases at the Wakefield Asylum, given by Dr (now Sir) James Crichton Browne, I had the privilege of witnessing demonstrations on the localization of the functions of the brain, given by Dr (now my distinguished friend Sir) David Ferrier, whose remarkable discoveries, along with those of Dr Hughlings Jackson, rendered possible the subsequent brilliant work of the late lamented Sir Victor Horsley, who gave his life for his country in the great war.

¹ BRITISH MEDICAL JOURNAL 1889 II p. 113

The descriptions of the evacuation of localized abscesses of the brain, of the treatment of Jacksonian epilepsy, of the removal of cerebral tumours, of the extraction of bullets and other foreign bodies, and of many other operations, would sound like a romance did time permit of a description. These operations, many of which I have been privileged to perform both in civil practice and during the war, especially in the Dardanelles campaign, are among the great advances during the past fifty years.

The surgery of the spinal cord and of the nerves, all rendered possible by researches in anatomy and by Listerian methods, would need a volume to record, and during the war these improvements in treatment have been of infinite service.

Fractures

The treatment of simple fractures, some by wiring the bones, from the first cases of fracture of the patella wired by Lister to the more frequent wiring of other bones by my friend Sir Arbuthnot Lane, and the innumerable cases of compound fracture, especially of the femur, treated by Thomas's splints and other special appliances, and with an infinite care in dressings, have completely revolutionized this branch of surgery, leading to the saving, during the war, of many thousands of lives and limbs that must otherwise have been lost.

The enormous amount of valuable orthopaedic work done during and after the war in the various war hospitals, chiefly under the direction of that master of orthopaedic surgery, Sir Robert Jones, has resulted in a great saving of deformities among wounded soldiers. The importance of orthopaedics in civil life is shown by the valuable work of the orthopaedic department in the Leeds Infirmary, in which no fewer than 910 operations are recorded in 1924.

Surgery of the Prostate

The operation of prostatectomy initiated and carried to perfection (as shown by specimens in the museum of this Medical School) by my late colleague and friend, Arthur Ferguson McGill, one of the surgeons to the infirmary, whom to know was to love, has been of infinite service in prolonging life and adding to the comfort of thousands of elderly men, the remainder of whose lives would otherwise have been one of torment and sorrow. Had that great surgeon been spared to work for a few more years, I feel sure that his skill as a surgeon and his original and fertile mind would have been of still greater service to the profession and to mankind generally. It seemed to some of us very hard that the reward of his labours should have fallen to others, but fortunately the operation was taken up later, where he left it, by the late Sir Peter Freyer, in whose able hands it was carried out so successfully that in 1912 he reported in the *BRITISH MEDICAL JOURNAL* 1,000 operations of complete prostatectomy.

Surgery of the Heart and Lungs The X Rays

The idea that wounds of the heart are necessarily fatal was exploded some years ago, when Jamain collected 121 cases, of which 16 recovered. Tapping the pericardium for serious effusion and draining it for pus have been frequently performed. The experiences of the war, in the repair of heart injuries after bullet wounds and in the removal of bullets, have added considerably to our knowledge of cardiac surgery, and a number of cases have been recorded in which wounds of the heart have been sutured. In 1911 I reported two cases in which, after removing tumours of the chest wall, I had to excise considerable portions of the pericardium, and in which the gaps in the pericardial wall were successfully closed by flaps taken from the pectoral muscle.

Pulmonary surgery was one of the great triumphs of the surgery of the great war, and many lives that must otherwise have been lost were saved in the casualty clearing stations in France where I saw cases treated by the radical method of removing or bending back one of the ribs, freely incising the pleura so that the hand could be passed within the chest to draw out the injured lung, in order to arrest bleeding, remove bullets, and stitch up wounds in the lung. After washing out the pleural cavity the lung was returned, the pleura was sutured and the outer wound closed. These and other operations on the lungs and pleural cavities have paved the way to the more radical treatment of many chest cases in civil practice.

The wonderful discovery of the x rays by Poentgen has proved of so much value in the diagnosis of fractures and other

bone injuries and diseases, in the discovery of calculi in the kidneys and ureters as well as in the pancreas and bile passages, in the localization of foreign bodies in the heart, the lungs, the oesophagus, the stomach, the intestines, and in various parts of the body, in the diagnosis of diseases of the stomach and intestines by observing the passage of bismuth test meals, in observing the size and pulsations of the heart, and in many other ways, both for diagnosis and treatment, that there is now in every well equipped hospital an x ray department, in which much valuable work is being carried out by experts in this new branch of medical practice.

Pasteur's Influence on Medicine

The influence of Pasteur's work in medicine has been no less than Lister's work in surgery, for the germ theory of disease has led to a knowledge of the causes of the various infective and many other diseases, and by means of vaccination or protective inoculations to the prevention or relief or cure of many of them, for instance, tetanus, diphtheria, typhoid fever, cholera, spenic fever, malignant pustule, hydrophobia, staphylococcal diseases, such as boils, carbuncle, osteomyelitis, and acne, and some of the streptococcal infections. In the war many thousands of lives were saved by the preventive injections of antityphoid serum, with which we were all inoculated before going out to the front, and by the injection of antitetanic serum into every wounded soldier on the battlefield before reaching the casualty clearing station.

In obstetric medicine the influence of Pasteur's teaching, and his bold exposure of the carrying of puerperal infection by the direct conveyance of germs through dirty hands, instruments and dressings of those attending the lying-in woman, brought about such a change in the death rate as to appear almost miraculous. The saving of life has been almost as great as that brought about by the antiseptic system in surgery. Puerperal fever, that terror of the lying-in woman, has been practically abolished. For instance, in the maternity department of the Leeds Infirmary during 1900 there were 547 women delivered without a single maternal death.

Of Pasteur's many other discoveries and victories there is no time to speak, but I ask my audience, Was there ever such a benefactor, not only to his country, but to humanity in general and to the world at large? His life rings with the spirit of service.

Cancer

On December 1st, 1904, I had the honour of being appointed by the Council of the Royal College of Surgeons to give the Bradshaw Lecture. My subject was Cancer and its treatment. Although acknowledging that we really know nothing of the true cause of cancer, I ventured to disagree with the conclusion of the superintendent of the Imperial Cancer Research Fund, that it is not permissible to seek for the causative factor outside the life processes of the cells, and suggested that the cause might be found in some of the ultra-microscopic organisms that are known to be the causes of various diseases, such as measles, scarlet fever, small pox, and cerebro spinal meningitis.

The wonderful work of Dr Gye and Mr Barnard, F.R.S., recently published, seems to point to the possibility of their having discovered a filter passing organism which they believe, as the result of much careful experiment, to be the real cause of cancer. The epoch making discovery in microscopy that, by using the short rays of the violet end of the spectrum or the x rays to illuminate the object and a specially constructed microscope, the filter passing organisms can now be seen, may be the key that is to unlock another pathological problem, as not only may we be able to see and possibly isolate the various filter passing germs, which are no longer ultramicroscopic, but to isolate the cancer germ itself, and if so the possibility of finding a vaccine or serum as a preventive or cure of the disease. It is reasonable, therefore, to believe that successful treatment may be, within a not far distant period, an accomplished fact. This would indeed be a triumph of discovery to the credit of this half century. Until such a discovery is completely established let us not forget that, by the early diagnosis and the complete removal of the growth along with the nearest chain of lymphatics and glands, cancer is frequently a curable disease, as I know from my own personal experience in a large number of operations, in a certain number of which there has been no return over a period of several years.

Conclusion

In the time at my disposal I have tried to show the immense progress that has taken place in surgery during the past half century. I have also tried to show what a close connexion exists between the science and art of our profession, and how very necessary it is, if we are to continue our march of progress, that experimental research should not only be untrammelled by factions and unreasoning opposition, but that it should receive greater recognition, encouragement, and support at the hands of the public. An even closer alliance between the physician, the surgeon, the pathologist, the bacteriologist, and the physicist is desirable, as the time is coming when preventive measures, some of which I have portrayed, will save much operative work, and when it will be thought a greater triumph to prevent than to cure disease.

It is quite evident that methods which were considered sufficient years ago are totally inadequate today. We may modify but we cannot prevent the world's advance, and while times change men change with them. The medical profession is imbued with a spirit that half a century ago was undreamed of. Not only have apparently insurmountable difficulties been overcome, but habits of thought have been attained which have made such achievements possible, and a scientific attitude of mind has become characteristic of our profession, as it has of the leaders in every branch of the world's progress.

THE MEDICAL CAREER PREPARATION AND EQUIPMENT

ADDRESS BY SIR HERBERT WATERHOUSE AT CHARING CROSS HOSPITAL

The prize distribution at Charing Cross Hospital Medical School took place on October 5th, when Sir Herbert Waterhouse, M.D., F.R.C.S. (consulting surgeon to the hospital), gave an address.

The dean of the school (Dr W. J. Fenton) mentioned in his report that, although a decline in the number of students entering had been anticipated, there was practically no diminution. The students and post-graduates now in the school numbered 150 and 13 men and 19 women had qualified during the past year. The post-graduate class had been attended with marked success, and it was hoped to extend this work very considerably.

Sir HERBERT WATERHOUSE, after a reference to his own long association with Charing Cross, remarked that it was a pleasant fact that in the study of medicine each succeeding year was less of a drudgery and more interesting than the year before. During the earlier years the study of anatomy might be found wearisome, and dissecting somewhat unpleasant, but this foundation of professional knowledge must not be neglected, for a good knowledge of anatomy could only be acquired in the dissecting room, and surgery, as one of his old teachers used to say, was only common sense applied to anatomy. With regard to lectures, he could not hold the view, popular in some quarters, that they were useless, although in his own student days he thought them more numerous than was necessary. He advised students to keep their reading always a few days ahead of their lectures so as more intelligently to assimilate the latter. It was only when a start was made on clinical work in the hospital, however, that the real fascination of the study of medicine began to be appreciated. It was a good plan for each student to choose his or her own physician and surgeon and attend the man so chosen in all his visits to the hospital. The student who flitted from one clinical teacher to another would doubtless learn much of value, but he would not see the same cases treated throughout the whole of their stay in hospital, and he would not acquire the same personal knowledge of disease and its treatment as he would by the adoption of the other plan. If a student was constant in his attendance upon the visits of his chosen teacher he would insensibly follow that teacher in his mental processes, and would find himself doing almost instinctively, what the teacher himself was likely to do in similar circumstances. The speaker had had the good fortune to be house surgeon to the late Sir William MacEwen. For six months he studied his great intellect as closely and devotedly as he was able, and in later years he often found himself doing something instinctively, and, on pondering the

matter, realized that he was following the example of his great master.

During their final year students would do well to devote their attention to special departments, particularly those for diseases of the eye, ear, and throat. These important branches of surgery were usually neglected by students, to the detriment of their patients later on. If every surgical examination paper contained a question on diseases of the eye, ear, and throat, these important subjects would no longer remain in their present comparative obscurity. Immediately after qualification and registration, the young medical man or woman would do well to join one of the medical defence societies. The majority of patients were grateful and appreciative, but now and again one was found who was cantankerous and litigious, and such a one had no difficulty in discovering a solicitor to encourage him. The newly qualified doctor would also do well to obtain a resident appointment as house surgeon or house physician (preferably both). It was impossible to overestimate the value of such a post. He had never known anyone consider as wasted the time spent in holding resident hospital appointments. After a profitable year as a hospital resident, the young medical man or woman would be well advised, circumstances permitting, to study abroad for at least one session. Foreign study widened a man's mental outlook and helped him to get rid of many of the faults of insularity. It was an enormous advantage to a practitioner to have a sound knowledge of French and German—languages so important for scientific medicine.

The purpose of some of those he addressed would, no doubt, be a specialist career, but the large majority would be content with the role of general practitioner. In the speaker's opinion a really good general practitioner represented the highest development of the profession. It was comparatively easy to know practically all there was to be known about one branch of medicine, it was far more difficult to know—as some first-rate general practitioners of his acquaintance did know—almost as much about every branch. Of the general practitioner three great things were required. The first was a thorough knowledge of medicine in all its branches. The second was the faculty of inspiring confidence in a patient, and in this connexion he urged practitioners not to be too chatty with their patients, they might find themselves contradicting at one visit what they had said unwittingly when they visited the patient before. 'If you are certain of your ground, speak but little, if you are not certain, speak less.' The third qualification was sympathy, which must never degenerate into sentimentalism such as he had heard in consultation at some bedside. Sympathy in the practitioner was an invaluable, indeed an essential, thing, but it must be blended with firmness and decision.

The annual dinner of past and present students of Charing Cross Hospital Medical School took place on October 5th at the Adelaide Gallery (Gatti's Restaurant), and was well attended. Dr W. J. Fenton was in the chair. The only toast of the evening was 'Our most illustrious doctor, His Majesty the King,' which was duly honoured. There were no speeches, but several anecdotes and fisherman's yarns were told. During the evening Mr John Goss with the Cathedral Quartette gave a selection of songs, and Mr Hubert J. Foss accompanied on the piano.

MEDICINE AS A CAREER FOR WOMEN

ADDRESS BY SIR CHARLES SHERRINGTON AT THE LONDON SCHOOL

The inaugural address at the London (Royal Free Hospital) School of Medicine for Women was delivered on October 1st by Sir Charles Sherrington, O.M., President of the Royal Society. The dean of the school, Dame Louisa Aldrich-Blake, presided.

Sir CHARLES SHERRINGTON said that he imagined that in this particular school, whatever might be the case in any other, all the students desired to enter the profession of medicine for no other reason than that medicine really appealed to them. That in itself was a pledge of enthusiasm, and no small asset to student and teacher alike. In the nature of things there were not so many callings open to women as to men, but medicine at least offered to women the opportunity of earning their

living. The average annual earnings of medical practitioners had been estimated at between £500 and £600, a low figure, but not a discouraging one in the present era of national economy and fortitude, and a figure which applied equally to women and to men. General practice represented the main path of the profession, but there were other far from negligible services, such as consulting and specialist work, the medical branches of Government departments, and municipal and county posts, and all these fields also had been entered by women.

But it was as true of women as of men that they did not live by bread alone. Medicine had been termed, with some justice, a poor trade but a noble profession. One of the things which made it attractive was that it was not only an honourable art, but a progressive science. Among the callings which were informed by progressive science it stood almost alone in its availability for women. Engineering depended upon a science perhaps equally progressive, but engineering was hardly a field in which women in any number could enter. The woman who yearned to be in the mid current of progress, and to feel and understand and further that progress, could rest assured that medicine would give her the opportunity in the fullest and most satisfying ways. He instanced some of the outstanding achievements of medicine within a period much shorter than that covered by living memory: for example, the control of many infectious diseases in the sense of disentangling the hold of the particular infective agent, the progress made in the relatively new subject of serology, the turning of the position with regard to deficiency diseases (in which victorious campaign women had borne a conspicuous share), the recent research in cancer, the discovery of insulin—these and other modern instances, selected at random, were well calculated to justify enthusiasm for medicine.

It was difficult (Sir Charles Sherrington continued) for the student to find time for all he had to learn. The introductory sciences had perforce to be curtailed because they were introductory, and economy of time was obtained by getting as much as possible of the introductory science done in the ordinary school years, and thus was the more advisable because the science subjects were to dry really essential to general education. He wished there could be found in the curriculum a place for teaching the principles of scientific psychology, for a grounding in the modern study of this subject was a great help in a professional career. With regard to the sciences which came later in the curriculum, these must all be regarded as a part of medicine itself. Differentiated as they necessarily were, and dealt with by separate specialist teachers, they were essentially one. The more that histology, anatomy, physiology, biochemistry, bacteriology, and pathology were all made to overlap and integrate, the better would all and each of them be grasped.

Medicine had two aspects—that of a science and that of an art. At their extremes the science and the art were clearly distinct, but in the middle region they were scarcely to be separated. As to what science was and what art was, he would take refuge in saying that all definitions were difficult and all comparisons odious. But he had seen such a thing as branding in some hands an art and not a science, in some an art and a science both in others a science but not an art. Science had laws which were quite unbreakable, hence Bateson's wise advice, 'Cherish your exceptions, for in nature every seeming exception was but obedience to another law. Art, on the other hand had laws which changed. The laws of the Romantic school of yesterday were not those of the Classic school of the day before. Hence the stability of medicine, which had become scientific. Fashions in branding might change, the principle of asepis always remained. But the point was that science and art dovetailed in medicine. It was a mistake to suppose that the division between science and art in medicine corresponded to the division between the laboratory and the ward. Science could enter into the handling of a case in the ward or in the out-patient department just as much as into laboratory observation. In medicine the clinical and the laboratory studies, each supported and fructified the other. The laboratory and the clinic each put its question in its own way to the problem before it; each knew its own laws, the tactics of each were independently pursued, but the problem was common to both. Term work was the happy and proper counterpoise to the competition which was so largely the rule of life. It was teamwork that built the cathedrals of a former age, and in this day of scientific medicine it was rearing something not less glorious.

Women seemed to be specially fitted for term work. He deprecated anything which would interfere with the freest co-operation between women and men. Women and men, working together, eluded and amplified each other's powers. The superimposed portraits (on the Galton principle) of men and women doctors might yield a composite prophetic picture of the ideal physiognomy of the profession. Women and men were not wholly unlike. There was something of man in woman, and something of woman in man. The existence of that school and its success showed that woman's rightful place in medicine was won, not by running at the possession of man's particular qualities, but by applying to medical work her own womanly nature. It seemed to him regrettable that the London County Council should have made a regulation that married medical women were ineligible for medical officerships. It had been estimated that 30 per cent of medical women married, though the figures for former students of that school were higher than that. The fact that women should enter and practise medicine freely was only another evidence of a progressive profession.

Those who went first along any path found it more lonely and difficult than those who followed after, and the school did well to remember with pious honour those who had led the way. All new social adaptations came slowly. Reform was not, as Rousseau thought, a simple return to nature. Perhaps, like the ancients, he was of opinion that we were descended from the gods. But after him came Darwin. The speaker, as a mere man, had had many reminders of mental kinship to primitive forebears. When he kept chimpanzees in his laboratory he was accustomed to visit them every day, and on one occasion, after leaving the room and locking the door, it occurred to him to turn back and see what the chimpanzees were doing immediately after his departure. He stooped and looked through the keyhole, and on the other side of the keyhole was the eye of a chimpanzee!

The convincing logic of your case stands plain to me. Sir Charles Sherrington concluded. "One of the things this school has proved is that women are well able to fulfil the expanding social duties that send them forth. Every case of sickness is not only a problem for medical science and art, but the suffering of a fellow creature, and women at least will not forget that. There is a story of a man who, after being refused by a lady, entered a medical career to harden his heart! But it is wholly a mistake that medical routine tends to blunt the feelings. Egotism may harden the heart, but knowledge never. Medicine enhances compassion and instruments it. Pure science, it is true, is intellectual and abstract, like mathematics, but at the bedside the case is always concrete. Science teaches humility, and humility is close to sympathy. Sympathy armed with understanding is surely what medical women stand for. I would assure those who by reason of their enthusiasm for medicine enter upon it in this school that their enthusiasm is well founded."

ST BARTHOLOMEW'S HOSPITAL

ANNUAL DINNER

THE annual old students' dinner of St Bartholomew's Hospital was held this year again in the Great Hall of the hospital, and the chairman, Mr JOHN ADAMS, F.R.C.S., was supported by a large and distinguished gathering.

After the health of the King, its patron, had been honoured, the toast of 'Prosperity to St Bartholomew's Hospital' was proposed by the chairman, who remarked that no hospital in the world had such traditions as theirs, which dated back more than 800 years. In the absence through illness of the treasurer, Lord Stanmore, the toast was responded to by Sir William Lawrence, Bt, senior almoner. He said that the preliminary task of the reconstruction committee was well in hand, plans and sketches had been drawn up, and these would be submitted soon to a court of governors. The plans for the rebuilding of the hospital provided for more than 700 beds on the present site, and for a paying patients block with upwards of 80 beds. The historic Great Hall so dear to the hearts of them all, would be left undisturbed, and in the reconstruction of the hospital the future development of its medical college had not been forgotten for the greatest asset of Bart's was its old students. In proposing from the chair 'Prosperity to the Medical College' Mr John Adams spoke of the splendid

record of the school from generation to generation, and of the great progress made since he entered in October, 1868. The school then numbered 223 students, this year there were 700, and of these 80 per cent were taking university courses. Recent honours conferred on St Bartholomew's men were Sir Thomas Horder's K.C.V.O., the well-merited knighthood of Mr James Berry, Sir Humphry Rolleston's appointment to the Regius Chair of Physics at Cambridge, and Professor Lovatt Evans's election as F.R.S. Mr McAdam Eccles, in responding to the toast, said how glad they all were that this should be proposed by John Adams, a beloved old student and still a Bart's man. The departments of Physics, Physiology, and Pharmacology were now established in the new building on the other side of Giltspur Street, but Anatomy still awaited better quarters. The staff now included four professors of the University of London, and he looked forward to seeing these chairs endowed for research. Lastly, he mentioned the work of the deep x-ray therapy department, second to none in the country, and the aid given in this and other directions by the physicist to the hospital, Professor Hopwood. The health of the guests was submitted by Sir Anthony Bowlby, Bt, who said of the representatives of the governing body that, like their predecessors, they loyally co-operated with the staff in all work for the hospital and college. He welcomed the presence of the medical heads of the three Services—Lieut General Sir William Leishman, D.G.A.M.S. (the first who had ever climbed to the top of the tree through his purely professional work), Surgeon Vice Admiral Joseph Chambers, Medical Director General R.N., and Air Commodore David Munro, R.A.F. Another guest, Sir Archibald Garrod, though one of themselves, was present that evening as Regius Professor of Medicine at Oxford. Sir John Bland Sutton, Bt, in reply, recalled some personal associations with Bart's: his deep affection and regard for the memory of Sir James Paget, his honorary membership of the Abernethian Society, his appreciation of the help given to him on the Council of the Royal College of Surgeons by Bart's men, notably by his predecessor in the presidential chair, Sir Anthony Bowlby, and his long friendship with John Adams. The last toast, received with great enthusiasm, was that of The Chairman, proposed by Dr W. Langdon Brown, who described John Adams as the youngest of old students, and one who, amid all the pressure of a long life of busy general practice, had found time for scientific work and study. After a few words in warm acknowledgement from the chairman the company broke up, to meet again in the library for coffee and gossip.

ST MARY'S HOSPITAL

ANNUAL DINNER

THE annual dinner of St Mary's Hospital Medical School was held on October 5th, at the Courtauld Rooms, Great Queen Street, the chair being taken by Mr Leslie Paton.

In proposing the toast of 'St Mary's Hospital Medical School' the chairman quoted Ecclesiasticus on the value of music combined with good wine and brevity of speech. He paid a sympathetic tribute to the memory of Sir Anderson Crichtett, and spoke of his kindness of heart and great power of inspiring co-operation. Of the three functions of a teaching hospital—namely, the care of the sick, research, and its teaching function—the last was perhaps the greatest, since it resulted in the spirit of the hospital being reflected throughout the world. If the teaching was well done the remaining two functions of the hospital would be similarly successful. St Mary's had always enjoyed a great reputation as a teaching hospital. In reply to the toast Mr A. R. Prideaux, chairman of the hospital board, referred to the financial position of the hospital and to illustrate the enthusiasm inspired by a great hospital he related how Mr Otley, the late assistant engineer had left £1,200 to the hospital the greater part of his estate, although he had received a salary of no more than £3 to £4 a week. The x-ray department was now complete and in good working order, deep therapy and electrotherapy for children could now be provided on the most modern lines. Within the next few days the hospital's wireless installation would be complete, thanks to the readers of the *Daily News*. Dr C. M. Wilson, dean of the medical school, also replied to the toast. He mentioned the

very gratifying attendance at the post graduate course held during the previous week end. One of the advantages possessed by the hospital was the relatively great possibility of medical students obtaining house appointments. The chairman's health was proposed by Dr R. H. Miller in a witty speech.

LONDON HOSPITAL

OLD STUDENTS' DINNER

THE annual dinner of the old students of the London Hospital was held on October 1st at the Trocadero Restaurant. The chair was taken by Sir Hugh Rigby, K.C.V.O., senior surgeon to the hospital, and nearly 200 old students were present. The chairman congratulated the hospital on its great and increasing prosperity. He said that the school showed no signs of "birth control," and though labour might sometimes be difficult, his sons were more numerous than ever, and as devoted as ever to the mother who gave them birth. Personally, thanks to the wizard hand of Lord Knutsford, the hospital had never been more prosperous, and the appreciation which laymen felt for its work was well illustrated by the generous gifts of £10,000 each from Lord Besset and Mr Barron for a clinical theatre and a pathological laboratory respectively, as well as by the latest gift of £50,000 from an anonymous donor for research. With the development of the Medical Unit, of the system of annex hospitals, and of changes in the organization of the receiving room and the out-patient department, many old traditions were passing away, but he hoped that nothing would ever be done to disturb the responsibility with which the residents were entrusted, to which they so largely owed the splendid type of practitioner whom everyone associated with the hall-mark of the London Hospital. Team work was the great demand of the present day, but nowhere could be found a more united or a more devoted team than the past and present students of the hospital which he and his audience were proud to own as their mother.

WESTMINSTER HOSPITAL

At the opening meeting, on October 1st, of the session of the Westminster Hospital Medical School, after the introductory address, of which a report appeared in our last issue (p. 623), a memorial tablet was unveiled by Professor E. A. Gardner, Litt.D., Vice-Chancellor of the University of London, in the pathological laboratories to record the gift of £20,000 by Mr A. J. H. Carhill for the promotion of pathological research. The dean, Dr A. S. Woodcock, in his annual report, drew attention to the fact that in the final medical examination an average of 80 per cent of the students had been successful, as compared with an average of 52 per cent for all the London hospitals. The various societies and clubs were flourishing, and there was now a possibility of obtaining a sports ground. The hospital had been the first to start a post-graduate and Fellowship of Medicine class, which had proved so successful that the experiment was being repeated. A course had also been arranged for officers of the Royal Army Medical Corps, and the War Office had asked that this should be continued twice a year.

The annual dinner of past and present students was held in the evening, with Dr H. B. Brackenbury in the chair. The proceedings were described by the chairman as being "not prosy, but convivial," and the meeting represented a family gathering of those who were always proud to call themselves students of the hospital. Dr Charles Roper, responding to the toast of Westminster Hospital students past and present, remarked on the gratifying increase in the percentage of old Westminster students on the staff of the hospital, and indulged in various reminiscences of old times. Mr R. G. Hodges replied for present students. These speeches were appropriately followed by a mixture of melodies popular twenty-five years ago with familiar tunes of the present day.

England and Wales.

HEART DISEASE IN WALES

DR G ARBOUR STEPHENS, consulting cardiologist to the King Edward VII Welsh National Memorial Association, contributed to the *Western Mail* for September 23rd an article on the prevalence of heart disease in Wales. He referred to the recent publication of the Medical Research Council in which Dr Matthew Young, in describing the geographical distribution of heart disease in England and Wales, pointed out that the three Welsh counties of Denbigh, Carmarthen, and Cardigan headed the list of death rates. Among women in Carmarthenshire it reached the high figure of 3.151 per 1,000 for women over 25 years of age. In Cardiganshire and Pembrokeshire, where there were no specially adverse industrial conditions, the death rates from heart disease were very high, whereas Glamorganshire, where the industrial strain was heavy, came low on the list. Dr Stephens remarked that the lowest mortality from heart disease in Wales was in Anglesey, and showed that the moist atmosphere associated with an island was not an important element in causing the disease. Carmarthenshire, with its very short sea coast, had a high mortality. He found, similarly, that housing accommodation could not be incriminated, since it was very inadequate in Glamorgan, where the cardiac death rate was low. The fact that Cardiganshire and Carmarthenshire showed a high death rate from heart disease, and were also noteworthy for the incidence of tuberculosis, seemed to Dr Stephens to indicate that there was a close connexion between rheumatism and tuberculosis. Both diseases, he stated, occurred in persons with a particular predisposition, which, in his opinion, was very closely associated with, or even due to, a lowered vitality caused by poor or injudicious feeding. He added that Cardiganshire and Carmarthenshire were drained of their milk and eggs for the benefit of the industrial areas, and that such nutritious Welsh foods as "cawl" and "flummary" had given place to tea and white bread. Dr Stephens, therefore, appealed for careful and widespread attention in Wales to the provision of more nutritious foods, especially those containing calcium.

THE LATE DR GORDON DILL

At the third annual general meeting of the members of the British Provident Association for Hospital and Additional Services, held on September 21st, a resolution, moved by Mr W McAdam Eccles (honorary secretary), and seconded by Sir Arthur Stanley, was adopted, expressing great regret at the death of their colleague Dr J F Gordon Dill, and placing on record their high appreciation of the public-spirited enthusiasm he had for long displayed in connexion with the establishment of schemes designed to assist the voluntary hospitals of this country, while at the same time benefiting the community in need of the services of those institutions. The resolution further recorded that it was to Dr Gordon Dill's imaginative faculty and his statesmanlike outlook that the association owed its conception and establishment, and that as its honorary secretary he gave of his time and energies without reward, other than the warm and sincere admiration of his colleagues and the gratitude of his fellow-citizens.

BRITISH SPA FEDERATION

The autumn meeting of the British Spa Federation was held last week at the picturesque little Lincolnshire resort of Woodhall Spa. Those present included Sir Ernest Baim (Hullington), Alderman T H Cooper (Buxton), Sir George Hastings (Strathpeffer), Alderman Stewart (Cheltenham), Mr John Hattou (Bath), honorary secretary of the federation, and representatives of all the leading British spas. The efforts the home spas are making to meet the severe competition of their foreign rivals were reported, and the respective advantages discussed and decided upon further steps to be taken in this direction. On the score of efficiency and completeness of equipment the British spas fear no comparison with those abroad, and through the federation they are endeavouring to thrash out their own problems which in many ways resemble those with which so many British

industries are faced to day. The important question of spa treatment for insured persons suffering from rheumatic diseases was further considered. The British spas are unanimous in their desire to see the benefits of mineral water treatment made available for those who have hitherto been unable to afford it, and a special subcommittee, consisting of representatives of Bath, Buxton, and Harrogate, was appointed to go into the complicated details which would have to be settled to enable this scheme to work as the federation intends it should work if it is adopted—namely, to the satisfaction of the insured patients and their doctors, and at the same time without interfering with the routine and comfort of the ordinary visitors who now go to the British spas for the cure.

CENTRAL MIDWIVES BOARD

The Central Midwives Board for England and Wales met on September 24th for a penal session, and again on September 25th, for the ordinary meeting. Sir Francis Champneys, Bt, presided. Consideration was given to the draft of a proposed revised regulation under the Public Health (Ophthalmia Neonatorum) Regulations, 1914, and copies of draft circulars intended to be addressed to certain local authorities in connexion therewith. The Board welcomed the proposed regulation, which should have the effect of settling the long standing difficulty in the matter of dual notification of ophthalmia neonatorum. It was resolved, however, to ask the Minister of Health to ensure that any circular should make it clear that, although a midwife would be relieved of responsibility as far as the local sanitary authority was concerned, she must still summon medical aid in all cases of inflammation or discharge, however slight, and notify the local supervising authority that medical assistance had been summoned—in accordance with the Board's rules. A letter was read from the Association of Municipal Corporations forwarding suggestions in connexion with the proposed conference between the Board and local supervising authorities. With reference to communications from the Society of Medical Officers of Health and from the College of Nursing, the Board recorded its opinion that all proper interests were adequately represented upon it, and that it was not desirable at the present time to reconstitute the Board. In reply to a letter from the medical officer of health for the county of Durham, the Board agreed that the professional association of a midwife with an unregistered medical practitioner was undesirable, and might come within the meaning of the word "misconduct" in Rule D 1. Approval was given to the draft of a memorandum on pemphigus in the newborn child, submitted by the chairman, and this was ordered to be printed and incorporated with the Board's rules. A resolution was adopted recording deep sympathy with the family of the late Dr W C Swaine and appreciation of the valuable service rendered by him as an examiner at the Bristol Centre. Miss Lily Anita Baker, MB, FRCS, was appointed to fill the vacancy at the Bristol Centre.

Scotland.

HOUSING IN SCOTLAND

At the invitation of the Glasgow Corporation the Prime Minister, on October 1st, formally opened the Knightwood and Kelmsdale housing schemes. The Knightwood scheme will provide accommodation for 15,000 people. It will form one of the most extensive garden cities in Scotland, covering about 650 acres on both sides of the Great Western Road at the existing boundary of the city. The total number of houses is 3,336, and in addition shopping centres, churches, parks, and recreation grounds will be provided. Building work is well advanced and provides three, four, or five roomed houses of attractive design. Mr Baldwin declared the scheme open, and said that there was no more hopeful and helpful work to-day than housing. The housing question should be taken to-day as the provision of shells had been taken in the war. Afterwards Mr Baldwin made a statement upon housing at the City Chambers. The Government, he said, had

decided to increase the Wheatley subsidy for the first 4,000 houses of alternate types in Scotland by a premium of £40. Though in England arrears in housing were being overtaken, they were, he believed, still accumulating in Scotland. In the past year under all the housing schemes fewer than 4,500 houses were built in Scotland, and this year it was not expected that more than 8,500 houses could be finished throughout Scotland, while the normal annual requirements of the country, on the other hand, could not be put at less than 10,000. The position was even worse than it appeared from these figures, for about 1,500 of the total 7,000 houses were being built in connexion with slum clearance schemes and were merely replacing bad houses by good ones. The root of the difficulty in Scotland had been that in the past they were accustomed to build in stone, and the great increase in the cost of building in this way had forced them to change over very largely to brick construction, for which the supply of labour was very inadequate. There was an accumulated deficit of some 150,000 houses. The only method suggested for dealing with this deplorable situation was to use the immense capabilities of the engineering industry, which at the present time was largely idle. He understood that the people living in steel houses found them very satisfactory in every way. Steel houses cost practically the same as brick houses, and though they would last at least forty years it could not yet be said that they would have the same life as the brick houses. If manufacturers were to lower their prices, orders must be large, not less than for 1,000 houses of any type. The Government was arranging with the Board of Health to act as a clearing house for orders from local authorities if it was desired, and to negotiate on their behalf the best possible price with the manufacturers concerned. The Government was prepared to give its strong support in carrying out a programme of auxiliary housing by the use of new methods of construction designed to produce houses rapidly, and at the same time to employ men who at present were idle. He appealed to Scottish local authorities generally, but especially to those of Glasgow and the surrounding districts, to make immediate application to the Board of Health with a view to participating in these schemes. There were at present only some 6,600 men employed in Scotland on local authority housing schemes, while there were over 60,000 unemployed in the city of Glasgow alone.

Correspondence.

TUBERCLE FREE MILK

SIR,—The interesting letter in your issue of October 3rd (p. 627) by Mr S. T. Irwin raises two important points of interest from the public health point of view.

1. It is possible, and by no means infrequent, for children to develop acute adenitis as the result of drinking milk containing bovine tubercle bacilli. The period of incubation is variable, but generally four to twelve weeks before the acute symptoms appear. The infection seems to occur through the tonsils, or through the base of a carious tooth.

2. A child which has been breast-fed or fed on pure milk is much more likely, when it receives tuberculous milk for the first time, to develop tuberculosis. The child which has been for some months fed on milk containing a few bacilli becomes to some extent immunized against bovine infection, and requires a heavy dose to produce adenitis or other forms of tuberculosis.

I have always maintained, rightly or wrongly, that all forms of surgical tuberculosis occurring in the human body are the result of infection by the bovine bacillus, generally conveyed by milk, and that a child which has been so infected is protected against primary pulmonary tuberculosis, which is always caused by the human tubercle bacillus. It is therefore of the highest importance to have a tubercle-free milk for children.—I am, etc.,

London, Oct. 4th.

NATHAN RAW

SIR,—The letter of Mr S. T. Irwin in your issue of October 3rd (p. 627) on the above subject implies a suspicion which is raising again that rather dangerous doctrine that the drinking of milk from tuberculous cows has a certain advantage in the production of an acquired immunity to tuberculous disease. As an explanation of the case which he describes I do not think that any such assumption is justifiable.

Infection with tuberculosis is not always a chronic affair. Although I have no exact figures to give I am perfectly familiar with the type of onset which he describes, a recent case known to me having occurred in the child of a personal friend, the child died later.

In none of these cases, of course, was it possible to define the actual period of infection, but the route onset, with congestion of, and perhaps pain in, the throat, and rapid swelling of the upper members of the deep cervical chain of glands, is not uncommon. In the child referred to a diagnosis of mumps was confidently made by the family practitioner, an epidemic of this disease being prevalent at the time. None of these cases had had tuberculin-tested milk, so that the question of lack of previous immunizing facilities as a result of infection from a milk source did not arise.

Is there not a perfectly reasonable explanation of these cases, even if we can exclude a sudden massive infection from a human source? The course that may follow an infection is surely determined by certain points which have been proved very conclusively by experimental means—the massiveness of the dose, the virulence of the organism, and that largely unknown factor mentioned by Mr Irwin, the lack of immunity of the patient. The actual period of time taken by the blood cells in transporting the infecting bacillus from the point of infection to the nearest glands is certainly very small.

Few escape infection at one time or another, but those are fortunate in whom the infection is postponed to the later years of childhood, and in whom the dose received is small and not repeated. Is this not the real danger? Repeated infection of a young child whose absorptive surfaces are active and whose lymph channels are free tends to lead to one result if that child has not the immunity conferred by a previous mild infection and the presence of a resulting concealed tuberculous focus on which the immunity depends. The chance of the presence of this depends on the chance of luck in receiving a regulated dose at an earlier period.

The fight for clean milk is an uphill one, and we should be particularly careful as a profession not to queer the pitch by suggestions which are not founded on a proper conception of the processes at work in tuberculous infection. The child quoted by Mr Irwin received at the age of 2 years the infection which he would presumably have got in any case at some time or another. If he started life with no specific immunity, then his response to infection would almost certainly depend on the size of the dose received and the frequency of the repetition of the dose. If he had received a small single dose it might, if absorbed, have produced the small lesion necessary for the production of immunity. If he succumbed suddenly to a large dose when it came, as many small children do, it is difficult to see what bearing the previous drinking of tuberculin-tested milk could have on the point at all.

Mr Irwin is asking, of course, for records of cases occurring under conditions similar to those of the case quoted, but let us be more than careful in our conclusions regarding the reasons for a particular course taken by the infection. We can all give disheartening records of disease, deformity and death in those to whom clean milk was unknown, and in whose case the milk concerned was, as in Mr Irwin's case, the probable source of infection.—I am, etc.

Ed. Fortune Oct. 5th

C CAMERON

SIR—Mr S. T. Irwin's interesting letter on "Tubercle-free milk" in the *Journal* of October 3rd raises a most important and practical point. I have heard of similar cases, some even more disastrous than the one quoted. By giving butter obtained from the ordinary market, I imagine that tubercle bacilli will occasionally

be given to the child. My practice with my own children has been as follows. Since weaning they have had certified milk from tuberculin-tested cows. The butter they have had, however, was ordinary country butter. When away on holiday where certified milk was unobtainable we decided to let them have one glassful of fresh unboiled milk a day, and at other times boiled milk. In this way we have hoped possibly to give an immunity without running the risk of a too massive infection.—I am, etc.,

F G CHANDLER, M.D., F.R.C.P.

London NW 1 Oct 3rd

A FRENCH VIEW OF FREUDISM

SIR,—It is with considerable interest that I have noted your review (September 19th, p 519) of Dr Laumonier's book, *Le Freudisme Exposé*, and the subsequent letter of Dr R MacD Ladell (October 3rd, p 627), who says that there is a "sufficient common ground between McDougall, Rivers, Adler, Jung, and Freud" to provide a solid basis for the understanding and treatment of neurotic conditions.

I enter a caveat, that in these matters we are not dealing with social or political compromises but with facts of nature, and that nothing can give a ground for understanding any phenomenon but the scientific study of the conditions that produce the phenomena. The citation of authorities is the method that was in vogue particularly prior to the day of Galileo in mechanics and of Pasteur in medicine, but it did not lead to the development of science.

Let me take one point out of many where a scientific examination riddles Freud's theories. He deals extensively with dreams, which depend on memory, and with memory itself, but nowhere in his writings, or in his work, is it possible to find any evidence, apart from a few shrewd observations and various extraordinary dicta, that he has seriously studied these subjects at all.

One of the chapters of my own book on psychology deals with memory, but in preparation for that part of the work I instituted a series of observations and experiments specially devised to determine certain points. Among the by-products of this work, which occupied many years, is the conclusion that much of what Freud lays down dogmatically is—I am a little alarmed at the dyslogistic terms that spring to my mind, but I will paraphrase them in the words—"not scientific."

Those who do not care to read my own book may refer to the notable work of Professor Dugas in the Bibliothèque Scientifique series *La Mémoire et l'Oubli*, where my experiments are frequently referred to and cited as decisive in the questions concerned.

But of what avail, even amongst scientists, is science in comparison with a popular boom launched with the great motive forces of sex and money?—I am, etc.,

London NW Oct 5th

ARTHUR LACHEN

SIR,—I gather from Dr R MacD Ladell's letter on your review of Dr Laumonier's "statement" of Freudism (*Le Freudisme Exposé*) that Freud's views on infantile sexuality are very clear—as clear as the proverbial "mud in a wineglass." If so, it is unfortunate that so many of Freud's disciples seem unable to decant the crystal vintage. As I hold it wise that cults should be investigated before they are condemned—whether they be hypnotism, homoeopathy, osteopathy, psychoanalysis, spiritual healing, or even spiritualism—I have submitted various patients to psychotherapists. I do not know whether the cures were wrongly selected, or whether the psychotherapist was unsuitable. Unfortunately the results have been uniformly unsatisfactory. From your review it seems to me that Dr Laumonier has suggested possible explanations for these failures.

As a result of these experiences in practice I view with some alarm the proposal implicit in the last paragraph of Dr Ladell's letter. From time to time appeals are made for the better treatment of some class of sick person. The argument is that at present they do not receive "anything like adequate treatment," "public facilities are all but non-existent." As a result the "economic loss to the community must be enormous." Consequently something—probably expensive—must be done at once. This line of argument, when applied, as Dr Ladell applies it, to neurotic

patients, must inspire one with terror. I trust that our psychotherapists will absorb the moral drawn by a reviewer from Dr Laumonier's book, and that they will submit the doctrine of Freud to further scientific investigation before they invite the public to embark on an anti-neurosis campaign.—I am, etc.,

Felstead Oct 5th

CHARLES BUTT

THE MORTALITY AND COMPLICATIONS OF DIPHTHERIA

SIR,—I regret that my letter (August 29th, p 383) inquiring as to the causes of the disappointing result of antitoxin treatment in checking diphtheria mortality, has elicited so little reply.

Dr Knivett Gordon (September 19th, p 542) thinks that the cause is that antitoxin is not given sufficiently early. Doubtless this is a considerable factor, and, if it were the principal or only cause, could constitute a reproach to the profession. But I cannot help thinking that other causes are at work. It seems to me that antitoxin has changed completely the clinical picture of diphtheria. True we do not get cases needing tracheotomy as formerly, but, on the other hand, we find almost invariable post-diphtheritic paralytic of greater or less severity, with increased tendency to heart failure, and also, I think, nephritis in a way in which it used not to occur. I still hope that some whose experience covers pie antitoxin days will give an opinion.

Dr Knivett Gordon, I am afraid, did not read my letter very carefully. The figures quoted referred to the whole country, and not to these districts, which are certainly no worse than others—rather better.—I am, etc.,

Brom grove Sept 27th

H CAMERON KIDD

MEDICAL WITNESSES TO EARLY CHARTERS

SIR,—In amplification of my remarks on this subject (BRITISH MEDICAL JOURNAL, September 26th, p 571), may I be allowed space in which to record one more charter with medical witnesses, which I have met with since sending in my paper? It will be found on page 101 of *The Chronicle of London*, by J H Round, in a charter of Geoffrey de Mandeville, Earl of Essex and Constable of the Tower. Round states that "it is difficult to resist the impression, from the appearance among the witnesses of a Templar and two doctors, that this was an act of restitution by the earl when he was lying on his death bed in 1144."

The medical witnesses are Einnulf and Iwodus, and they sign last. The Templar's name was Pagan. Without giving the text of the charter I may be allowed to abstract what Round says of the subject.

"In 1125 the 'soke' of the *Onlhtengild* was transferred by that body to Holy Trinity Priory. The land was in 'East Smithfield,' outside the wall from Aldgate to the Thames, and immediately adjoining the Tower precinct. The Priory having acquired the soke, complained that successive Constables of the Tower had encroached on this land to make a vineyard." This is followed by a long document in Latin and by a charter of King Stephen, in which occurs "in perpetuum terram suam de Smethefelda quam comes Gaufridus preoccupaverat ad vineam suam faciendam."

Einnulf and Iwodus, if in attendance at the passing of him whom Round speaks of as "the dreaded and unsuspicious earl," deserve to be remembered by the medical profession. Perhaps they helped in more ways than one in this act of restitution. Who knows what the effect of a mediaeval purge may have been on such a magnitude as Geoffrey de Mandeville?—I am, etc.,

London W Sept 30th

R R JAMES

COLLECTIVE INVESTIGATION OF RHEUMATOID ARTHRITIS AND ALLIED CONDITIONS

SIR,—I cordially agree with every word of Dr J S Kellett Smith's letter in your issue of September 26th (p 583). I foresee one difficulty, which we must try to overcome—namely, we must educate the public to understand the need for such investigation before we can hope for funds. That is a formidable undertaking, and it is our first task.—I am, etc.,

Jersey Sept 27th

SYDNEY WHITBART

Obituary

JAMES NIVEN, M A, LL D, M B, B Ch,

Late Medical Officer of Health, Manchester

DR JAMES NIVEN, formerly medical officer of health for Manchester, whose death occurred on September 30th while on a visit to the Isle of Man, was the son of Charles Niven, and was born at Peterhead on August 12th, 1851. He entered first at Aberdeen University, where he graduated M A in 1870. He then went to Queens' College, Cambridge, where he was bracketed eighth wrangler in the mathematical tripos of 1874 and was elected Fellow of his college. He took the degree of M A Camb in 1877, and, having decided to enter medicine, became a student at St Thomas's Hospital, and graduated M B, B Ch Camb in 1899.

He had the advantage, somewhat rare in the present day, of spending several years in Manchester in private practice before entering on an official career. He was first medical officer of health for Oldham from 1885 to 1894. Then he succeeded Dr Tatham, who had resigned the Manchester health officership when appointed to follow Dr Ogle as medical statistician at Somerset House. From 1894 until his resignation in 1922 Dr Niven worked on in Manchester, and his name will ever be associated with the health advancement of that great city.

In 1923, under the title *Observations on the History of Public Health Effort in Manchester*,¹ Dr Niven published an account of his work, which should be an inspiration and a stimulus to every health officer. The arrangement of the book shows the thoroughly practical bent of the author's mind. He begins in a fashion which would have seemed straight away the sympathy of Chadwick and Southwood

Smith. His first subject is the influence of dirt, and his opening statement reads "It will be found, I believe, that by far the most important influence which has governed the improvement of the public health in Manchester, apart from economic conditions, has been the removal of organic filth, whether without or within the habitations of the people." He proceeds, "Probably the next in importance has been the control of infectious disease." Also, "No less weighty in their effects have been the economical factors and the consequent diminution of poverty." On this triple foundation other things of highest importance are superimposed—the treatment of venereal disease, the control of tuberculosis, and of milk and food, improvement of housing, maternity and child welfare, and training at school. Much the largest section of his book is devoted to infectious diseases, which receive fuller treatment than, for example, maternity or child welfare. Dr Niven may perhaps on that account be regarded as old-fashioned—to which recusation he might possibly have replied that the younger men may be well-fangled, while an impartial referee might hold that there should be no lack of attention to either part of the service.

The judicious and unbiased character of Dr Niven's mind

¹ See BRITISH MEDICAL JOURNAL, 1923, vol II, p 468.

is well shown in his calm and careful discussion of two subjects connected with infectious disease—namely, the causes of the decline in prevalence and fatality of scarlet fever, and the influence of small pox hospitals on the spread of infection in the surrounding area. Looking back on his long and full experience, he quietly and, as it were meditatively, sets forth the various considerations relevant to each, and strains no point unduly in favour of one or another view.

Throughout his career he devoted very special attention to the control of tuberculosis, and to securing for Manchester a clean and safe milk supply. In both he worked in the closest harmony with the late Professor Sheildon Delepine, and Manchester has indeed been fortunate in having in its service two men whose functions and ideals, from the administrative side on the one hand, and the laboratory side on the other, combined so admirably for the benefit of the great community which employed them, and also of the country as a whole.

Niven was intimately acquainted with the views and policies of contemporary workers, and strove to adopt what was good in every one of them, combining them into an administrative practice of his own without magnifying any individual feature of it. In the control of tuberculosis he realized alike the importance of building up personal health in resistance of attack, and prevention of infection by sputum or otherwise in households where the disease existed. But he did not attach exaggerated value to institutional isolation as a means of protecting against spread of the disease. His view in 1923, as in 1906, was that "while the value of segregation carried out under suitable conditions is recognized, it is not believed to have exercised the influence claimed for it in the past. Much more is believed to have been due to growing prosperity, better and cheaper food, cheaper clothing, improvement in housing, increased facilities

for travel with consequent diminution of intermarriage, improvement in the conditions of labour, etc." But the working class houses of Manchester were mostly of five or six apartments, and the need for institutional segregation was not so great as in less favoured places.

The long fight which he, with the support of Professor Delepine, conducted for the establishment of a clean and pure milk supply for Manchester makes one of the finest chapters in the history of that great municipality, but even in 1923 he did not regard the victory as completely achieved. So long ago as 1894 he expressed the view that milk should be sold only in protected containers—that is to say, that the milk trade should be a bottle trade. Even yet that ideal is not completely realized. As regards the condition of milk production, he wrote in 1923 "The fact is that the great bulk of the cowkeepers have even yet no conviction which would enable them voluntarily to take the necessary measures of cleanliness—the kind of conviction, that is, which results in semi-instinctive action." And again he says "The fact is that the farmer is inert, and in spite of prolonged agitation and discussion the general public is little less so", so that now "The necessary measures of reform will have to be formulated and imposed by Government if clean milk is to be obtained." As a

member of the departmental committee on tuberculosis in 1912 Dr Niven took his due share in the work assigned to that body.

A direction in which he did almost pioneer service was in investigation of the influence of fly prevalence in the spread of infectious disease, especially of typhoid fever and summer diarrhoea.

There is temptation to extend the story of Dr Niven's activities into other spheres of municipal progress, but space forbids. He had a personality which commanded the respect and ensured the affection of all who had the privilege of his friendship. He was no orator. Slow of speech, reserved in manner, his learning was concealed by diffidence and modesty. He did not carry his heart on his sleeve, and quite possibly some part of the public may not have realized how big a man he was. If so, that has been their loss. But so far as the writer of this notice has observed, no health officer can have done more than, if indeed so much as, Niven in training, both in the spirit and practice of public health, so many assistants who have now achieved success and distinction in many spheres of public work. Dr Niven had conferred on him the honorary degree of LL.D. from Aberdeen University, and received much honour from his public health colleagues and contemporaries, including the presidency of the Section of Epidemiology of the Royal Society of Medicine and of the Section of Public Health at the Annual Meeting of the British Medical Association in Manchester in 1902.

J C M

Dr Niven was a widower, and is survived by three daughters, for whom much sympathy will be felt. He belonged to a distinguished family. A Cambridge wrangler himself several brothers were also wranglers. One was Sir William Davidson Niven, K.C.B., formerly director of studies in the Royal Naval College, Greenwich, and Fellow of Trinity College, Cambridge. Another was Charles Niven, D.Sc., F.R.S., professor of natural philosophy in the University of Aberdeen from 1880 until his resignation in 1922. Dr Niven's own bent towards, and distinction in, mathematics naturally led to the statistical presentation of public health problems in his numerous annual reports.

At the inquest held at Douglas on October 2nd a verdict of death from poisoning while temporarily insane was returned. Evidence given by a friend, Mr. Lang, deputy coroner for Salford, was to the effect that Dr Niven had become despondent since his retirement and had failed physically. There were no financial or family troubles.

Dr VERTER CLARK, who succeeded Dr Niven as medical officer of health for Manchester, has, in response to a request from us, sent the following tribute to his memory. The death of Dr Niven has removed one of the most eminent figures from the circle of public health and preventive medicine. His reputation on all subjects affecting the physical welfare of the people was certainly not exceeded by any of his contemporaries, and the solidity of his work in itself has raised a lasting monument to his memory. It is peculiarly within that circle of the section of medicine to which he devoted his life that his memory is most affectionately held, and his outstanding gifts and attainments revered, but his purely personal attributes are perhaps those which will linger most in the minds of those who had the good fortune to come intimately into contact with him. A man of unbounded courage and tenacity in support of his views he nevertheless exhibited in remarkable degree the combination of simplicity of character and very high intellectual ability found only in the kindest natures. There was no time when he was too pressed by public or private affairs not to be interested in the welfare of those surrounding him, and the sympathy and gentleness which characterized him in his personal relationships found expression not only in words but in actual personal and material help whenever that was possible to him. His innate shyness at times gave the impression to those who did not know him well of an abrupt personality, but no judgement of this nature lasted long if the personal contact with Dr Niven continued. His tastes like his life were quiet and simple, and his most intimate friends learned to regard him with an affection which is rarely accorded by

one man to another. The intensity of his diligence, and a passion for accuracy and completeness in all his work, inspired his staff with a like zeal, and his influence on public health in England in this direct personal manner will long be felt through the numerous medical officers now working in preventive medicine who owe their early training and instruction to him. We revere his memory as a departed master in his work, and we grieve at the loss of the trust of personal friends.

Dr R. G. McGOWAN (honorary secretary of the Manchester Division of the British Medical Association) writes: The medical practitioners of Manchester would, I am sure, wish to place on record their appreciation of the late Dr Niven, and their deep regret at his most untimely end. During his long service in and to the city he had many schemes to initiate and plans to carry out that might easily have aroused antagonism or voice among the general practitioners, but none of us, having met him personally, could nurse resentment long against Niven. The plain honesty of purpose, the desire to help, and the foresightedness of the man were too great for much resistance, and he earned us with him many times when a lesser man would have failed. Others can, and doubtless will, speak more fittingly of his attainments in his own special work, those of us engaged in general practice can speak with gratitude of the kindly manner in which those attainments were always freely at the disposal of those who wanted help in their work, and all who were in any sense his contemporaries can only feel that they have lost an old and valued friend.

A JUNIOR COLLEAGUE writes: All who have served under Dr James Niven will feel the sense of intimate personal loss caused by his tragic death. To the outside world he was an austere, severely conscientious, and capable medical officer of health. Another side of his character was presented to those of us who had the honour to work under his direction. Dr Niven had the gift of getting the best work from his subordinates—one could be certain that any work performed would meet with generous recognition. The value of such work was most often due to his inspiration and guidance, but his junior colleagues invariably received the whole credit. His kindly thought for his assistants followed them after they left Manchester, he kept in personal touch with many, and delighted in hearing of their advancement. An appreciation in the *Manchester Guardian* states that he was "so intensely simple as to puzzle sophisticated people"—it was perhaps this quality of mind which endeared him to children and which caused us to marvel at the ease with which he gained their confidence and affection. The feeling of personal allegiance which was called forth by his gentle and transparently honest character permeated his whole staff, and there are many old colleagues in whose thoughts the "old man" will remain as a much-loved and honoured memory.

SIR ALAN MANBY, K.C.V.O., M.D., F.R.C.S.,
Physician Extraordinary to H.M. the King

We regret to record the death, which took place at his home at East Rudham on September 29th, of Sir Alan Manby, for many years the trusted medical attendant of the Royal family in their home life in Norfolk. He was physician extraordinary to the King, and had been surgeon apothecary to the King and Household at Sandringham, and to Queen Alexandra, and physician extraordinary and surgeon apothecary to King Edward VII. His health had been failing for some months past.

Alan Reeve Manby was born on June 4th, 1848. His father, Frederic Manby, practised at East Rudham, as his grandfather had done before him. From Epsom College he was sent to Guy's Hospital, and obtained the L.S.A. in 1869 and the M.R.C.S. Eng. diploma in the following year. After qualification he served as obstetric resident at Guy's Hospital, and then went to join his father in the family practice. In 1888 he took the M.D. degree of the University of Durham, and in 1918 was elected a Fellow of the Royal College of Surgeons as a member of twenty years' standing. His first appointment to King Edward, then

Prince of Wales, as surgeon apothecary at Sandringham, was made as long ago as 1885, he accompanied King George and Queen Mary (then Duke and Duchess of York) as medical attendant during their tour of the Dominions in 1901. He received the honour of knighthood in 1903, and was created K C V O in 1918. He was also a Knight Commander of the Danish Royal Order of Dannebrog.

Sir Alan Manby was for many years an active member of the Norfolk and Norwich Medico-Chirurgical Society, and served as president in 1892. In 1896 he was president of the East Anglian Branch of the British Medical Association, and held office as vice-president of the Section of Obstetrics when the Association met at Oxford in 1904, and vice president of the Therapeutics Section at the Toronto meeting two years later. At the Annual Meeting at Ipswich in 1900 he had been honorary secretary of the Section of Pharmacology and Therapeutics. For seven years he was a member of the Parliamentary Bills Committee of the Association. He contributed a number of papers to medical periodicals, in 1873 he invented a flexible spiral probe, and in 1886 a modified form of lithotrite.

Sir Alan Manby married in 1876 Charlotte Anne, daughter of his neighbour the late Edmund Farrer, of Pettywards Hall, Swaffham. He is survived by Lady Manby, by his son, the Hon Mr Justice Percy Manby, Judicial Commissioner of the Federated Malay States, and Judge of the Supreme Court, Straits Settlements, and by his daughter, who is the wife of Dr F J Williams, surgeon apothecary to His Majesty's Household at Sandringham and to Queen Alexandra.

Dr MAURICE MOTTAM (Sibford Ferris, Banbury) writes May 1, as an assistant for five years to the late Sir Alan Manby add a little to what has already appeared? No one who worked under him could fail to be impressed by his loyal support in public and the help and advice which he gave in private. He was, I believe, a strong advocate of the apprenticeship system, and regretted its abolition. He held that both employer and employed had a very definite duty towards each other—that while the assistant should work honestly and well in his chief's interest it was equally incumbent on the older man to instruct the younger in all those matters appertaining to the conduct of a practice to which no attention is given in the ordinary medical education. He was insistent on the fact that a practice should be managed on business lines and held that this could be done without any loss of professional prestige. From the purely professional point of view his teaching drawn from a life's experience, was most valuable. Though a countryman, he was not perhaps a keen horseman as were some of his contemporaries, but, being a mechanic of no mean order, it is not surprising that he was found among the pioneers of the motoring movement when the transition from horse drawn to motor conveyance set in, and to such men we owe much of the luxury of the modern car, for they are luxurious by comparison his first car, if I remember rightly, having neither hood windscreen, nor pneumatic tyres. He foresaw how far reaching might be the effects of certain innovations, such as the introduction of certificated midwives, on the general practitioner. One cannot but feel that if every newly qualified man could put in one year at least as assistant to a man of Sir Alan Manby's stamp it would be greatly to the advantage of the profession as a whole.

JAMES W RUSSELL, M D, F R C P,

Physician Birmingham General Hospital Professor of Medicine, University of Birmingham

We record with regret that Dr James W Russell, senior physician to the Birmingham General Hospital and professor of medicine in the University of Birmingham, died on September 20th at Hay Tor, Devonshire, where he was on holiday.

James William Russell was a member of a notable Birmingham family which for several generations has been represented in the medical life of the city. His grandfather was a prominent general practitioner, his father a leading consultant, who was for many years honorary physician to the General Hospital. Dr Russell was born in Newhall Street, Birmingham, in 1863. He received his early education at the Edgbaston Proprietary School and proceeded to Cambridge, where he took the degrees of M B, B Ch in 1890 and of M D in 1893. He became a

Member of the Royal College of Physicians in 1893, and was elected a Fellow in 1905. After leaving Cambridge he studied at Guy's Hospital, London, and Queen's College, Birmingham. In March, 1891, he was appointed resident medical officer at the General Hospital, Birmingham, and fifteen months later he became assistant physician, holding the post until January, 1912, when he was appointed honorary physician. For some years before he became professor of medicine he was lecturer on clinical medicine under the Clinical Board of the University. He was consulting physician to the Birmingham and Midland Eye and Throat Hospital, the Royal Institution for the Blind, the Sutton Coldfield Cottage Hospital, the Dudley Guest Hospital, the Smallwood Hospital, Redditch, and the Corbett Hospital, Stourbridge.

At the Annual Meeting of the British Medical Association held in Birmingham in 1911 Dr Russell was vice-president of the Section of Neurology and Psychological Medicine. His contributions to medical literature were few by comparison with the scope and originality of his work. He was a true lover of music, and was one of those responsible, during the years immediately before the war, for a series of promenade orchestral concerts conducted by his friend Sir Landon Ronald, which performed invaluable service in raising the standard of public appreciation of music.

For the following appreciation we are indebted to Mr ALBERT LUCAS, F R C S, late senior honorary surgeon to the General Hospital, Birmingham. My friendship with the late Dr James W Russell dates back to 1891, when we were the senior residents at the General Hospital and were colleagues on the staff until his death. It was a great grief to us to hear of his death, although it had not been unexpected. Russell was a man who was not merely liked and respected but was greatly beloved by everyone—patients, nurses, students, and his colleagues. I think there was no physician in this city whose help was more sought after by practitioners and his colleagues in cases of serious illness in their own households. He was to me the type of a perfect physician—a sound teacher, a careful diagnostician, and one who, before everything, considered the interests of his patients. His health was never good, but he did not spare himself when he conceived it to be his duty to go to the hospital or elsewhere at any time of the day or night to see some urgent case, a most conscientious man it would be difficult to imagine. He was a most unselfish and considerate colleague, extremely modest and reticent, but possessed of a strength of character that was not at first obvious to those who did not intimately know him. We shall all greatly miss him.

A COLLEAGUE writes: James Russell was a man of a type rarely met with, combining outstanding ability and skill with a diffidence amounting almost to self-abasement. As a physician he was philosophical, learned, and possessed of a rare clinical instinct. He put his work, the good of his patients, and the interests of the General Hospital and of the medical school among the first considerations of his life. As a teacher he was pre-eminent. He was not in eloquent or a striking lecturer—he was not sufficiently dogmatic to be the latter—but he took wide views, never unduly protruding his own opinions, though he possessed strong opinions, but always giving a well balanced and comprehensive account of his subject. As a bedside teacher Russell was at his best. He never gave way to the temptation of teaching the transcendental, but made his students understand that their most important work in the wards was to learn the elements of physical diagnosis rather than to study rare diseases. Generations of students of the Birmingham school will be the first to acknowledge the debt they owe to Russell, both for his teaching and for the example he set them. He was indeed a "*Châlier sans peur et sans reproche*," who always took the line that he considered the right one, no matter what the consequences might be to him. The writer was associated with him in hospital and university work for many years, and, though differing from him at times, always realized that Russell had the highest motives for what he did, and that no thought of self ever prompted his actions. In Russell Birmingham medical life loses a loved and honoured leader.

SIR H R WHITEHEAD, K C B, F R O S,

Major General A M S (Ret.)

MAJOR GENERAL SIR HAYWARD READER WHITEHEAD, K C B, Army Medical Service (retired), died at Landhurst on September 28th. He was born at Grafton, Bucks, on July 14th, 1855, the second son of the Rev. T. C. Whitehead, headmaster of Christ's College, Finchley, and was educated at Charing Cross Hospital, taking the M.R.C.S. in 1877, and the F.R.C.S. in 1880, in which year he also took the L.R.C.P. Ed., and subsequently the D.P.H. of the London Colleges in 1890. Almost immediately after qualifying he was appointed assistant surgeon on the staff of Charing Cross Hospital, and also of the Royal Westminster Ophthalmic Hospital. He joined the Army Medical Department, now the R.A.M.C., in 1882, and it may be noted that at the same examination at which Whitehead entered the Army Medical Department the late Lieut.-Colonel A. W. D. Leach, who took first place for the I.M.S., was also an assistant surgeon on the staff of the Royal Westminster Ophthalmic Hospital.

Whitehead was gazetted surgeon in 1892, reached the rank of colonel in 1905, became surgeon-general in 1909, and retired in December, 1917. From 1891 to 1896 he filled the post of assistant professor of military surgery in the Army Medical School at Netley. When he left Netley he was sent to India, and soon after served on the north-west frontier in the Tirah campaign of 1897-98, when he was present at the action of Dargai, the capture of the Samragha and Aihangra passes, the operations against the Khani Khel Chitkani tribe, and those in the Bara Valley, was mentioned in dispatches in the *London Gazette* of April 5th, 1898, received the frontier medal with two clasps, and a special promotion to lieutenant-colonel. After his promotion to colonel, while holding in administrative post in India, he served on the north-west frontier again, as principal medical officer, in the Mohmand campaign of 1908, he was mentioned in dispatches in the *London Gazette* of August 14th, 1908, and received the medal with a clasp.

On promotion to surgeon-general in 1909 he was posted to the Southern Command, and in 1912 was transferred to the Eastern Command, and held this post for the first year of the war. In July, 1915, he was sent to Malta, and in March, 1916, was appointed principal medical officer of the British forces at Salonika, remaining there till September, 1917. For his services in the late war he was mentioned in dispatches in the *London Gazette* of December 6th, 1916, and November 14th, 1917, and received the K.C.B., having previously been given the C.B. in 1909. He was also a Knight of Grace of the Order of St. John of Jerusalem, and held the Commandership of the Legion of Honour, the second class of the Serbian Order of St. Sava, and the Greek Order of the Redeemer. He was the author of the article on tropical enteric fever in Davidson's *Hygiene and Diseases of Warm Climates*. In 1893 he married the second daughter of the late Colonel H. Cayley, I.M.S., but leaves no children. His nephew, Major N. T. Whitehead, M.C., R.A.M.C., is Government Bacteriologist in the Wellcome Tropical Research Laboratories, Khartoum.

The death occurred on September 27th of Dr. GEORGE SCOTT CARMICHAEL at his house in Edinburgh. Dr. Carmichael had been in poor health for some time, suffering from a cardiac affection. He was born in 1875 and educated at George Watson's College and at the University of Edinburgh, where he graduated M.B., Ch.B., with first class honours, in 1900, taking the M.D. degree in 1904. He had obtained several prizes and scholarships during his course of study, being Vans Dunlop scholar in 1896 and taking the Allan fellowship and Berney prize on graduation in 1900. After graduation he became house-physician to the late Sir Thomas Fraser and was subsequently house-physician in the Hospital for Sick Children, Great Ormond Street, London, and resident physician in the City Fever Hospital, Edinburgh. He returned to Edinburgh as assistant to Sir Thomas Fraser in the University department of materia medica, and while so employed carried out research upon the action of venom of *Bungarus coeruleus* (common lizard), which was published in the *Transactions of the Royal Society*, London, in 1904. He joined the College of

Physicians at Edinburgh as a Member in 1911, and in 1919 proceeded to the Fellowship of this college. For some twenty years before his death he had been in general practice in the Morningside district of Edinburgh. Here he carried on a large practice and enjoyed in a very high degree the confidence of his patients and the good will of the medical profession in Edinburgh, by whom his early death is greatly deplored.

IMPERIAL SOCIAL HYGIENE CONGRESS

STATEMENT BY THE COLONIAL SECRETARY

IN connection with the Imperial Social Hygiene Congress, held at the British Empire Exhibition, Wembley, a dinner took place at the New Princes' Restaurant, Piccadilly, on October 5th, in honour of the overseas delegates attending. The chair was occupied by the Right Hon. Sir Auckland Geddes, C.M.G., M.D., president of the British Social Hygiene Council (formerly the National Council for Combating Venereal Diseases), the body which had charge of the arrangements for the congress. Conspicuous among those attending were officers deputed by the Government of India and by provincial governments and Indian states.

The Right Hon. L. S. Amery, M.P., Secretary of State for the Colonies, in proposing the toast of "The Empire," said that not the least of the functions of the Colonial Office was to act as an Imperial Ministry of Health. Not that his department directly administered health matters, but in dealing with the different administrations which were directly dependent upon the Colonial Office one of the primary tasks was to create enthusiasm for the work of physical regeneration and the building up of healthy populations. That idea had found no greater champion than his famous predecessor, Mr. Joseph Chamberlain. Lord Cromer also did a great deal for medical work in the empire. In the Colonial Office much had been accomplished by the advisory medical committee, and there had been a steadily increasing recognition of the importance of medical service. His department was now considering in what way and in what form the medical side of the Colonial Office could be still further strengthened. He paid an eloquent tribute to the medical services in the colonies, and also to the value of medical missions, in Africa particularly. The most difficult task of all was to educate the colonial peoples themselves in the elements of health and sanitation. In most parts of the empire the teaching of these things mattered even more than most forms of book learning. He regarded imperial social hygiene as at once one of the most serious and most hopeful movements of the time.

Viseount WILFREDOW, in responding, said that there was nothing more important for the British Empire than to endeavour in every way possible to raise up a healthy, virile people in the future, and that was the purpose at the back of the British Social Hygiene Council. On returning from India he was very glad to have the opportunity of continuing some imperial service as a vice-president of that organization.

Sir AUCKLAND GEDDES said that the congress was an assured success, and he thanked Mr. Amery for making it possible. An essential part of government must come from a number of bodies comparable to the British Social Hygiene Council, which kept a necessary point of view steadily before Ministers and officials, and before the public also.

Sir ALFRED MOND said that the pioneers of the movement to combat venereal diseases had every cause to congratulate themselves. For an expenditure of £318,000 a year the figures for syphilis in four years had been reduced to less than one half, and the other figures also showed substantial reductions. In these days of economy there was one form of retrenchment which he hoped would never be made—the withholding of expenditure for stamping out disease. The legacy of his own tenure as Minister of Health of which he was proudest was the Imperial School of Hygiene, an institution which he hoped would in time render vast service in many directions, especially in tropical medicine. Sir WILLIAM SCROOPE proposed the health of the delegates and the toast was responded to by Sir CLAUDE HILL, director general of the League of Red Cross Societies.

In the course of the dinner messages were communicated from the High Commissioners for Australia, Newfoundland, and New Zealand, emphasizing the importance of the work of the congress and congratulating the organizing society on the new evolution in its history indicated by its change of title. Sir JAMES ALLEN, the High Commissioner for New Zealand said that the whole question of combating venereal diseases was receiving serious consideration and attention in his Dominion, where, quite recently, new legislation had been brought into being conferring additional powers on the authorities responsible for the prevention and amelioration of these diseases. At the opening meeting of the congress appreciation of the work done by the council was expressed by other colonial representatives, including the High Commissioners for South Africa and the Irish Free State, and by the Prime Minister of Malta. Representatives of the services also spoke to the same effect.

Universities and Colleges.

UNIVERSITY OF LONDON

The Rogers prize value £100 will be awarded for an essay on dissertation on the value of various methods of investigating disease of the pancreas, which must be received by the Vice-Chancellor on or before April 30th. The prize is open to all persons whose names appear on the *Medical Register* of the United Kingdom. Further information can be obtained on application to the Academic Registrar.

KING'S COLLEGE

At the meeting of the delegacy held last week Mr. Harry Gordon Reeves M.Sc. was elected as the first holder of the recently established Berridge Studentship. The studentships were founded this year on the occasion of the closing of the bacteriology and public health department and to commemorate the fact that this department founded in 1898 by Professor D. M. Crookshank, was the first academic department of public health in this country. One studentship of the value of £100 per annum is offered annually for research in physiology as applied to public health and the usual tenure is two years.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examination indicated:

FINAL M.B. CH.B. (Part II) in Public Health only completing Examination—C. L. Hyatt H. J. Satchwell

* Passed with distinction in Surgery

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, 5th George Street, Mr. J. M. P. Williams was admitted (after examination).

Medical News.

A COURSE of lectures on preventable diseases will be delivered at the Royal Institute of Public Health on Wednesday afternoons, from October 14th to December 16th. The lectures deal with medico-social problems, and include such subjects as the prevention of tuberculosis, rheumatism, cancer, infection in ships, and puerperal sepsis. Professor J. C. G. Ledingham will deliver the Harben lectures from December 9th to 11th inclusive, his subject being current problems in bacteriology and immunology. Further information may be obtained from the Secretary, Royal Institute of Public Health, 37, Russell Square, W.C.1.

A SERIES of lectures and demonstrations will be given at the Ancoats Hospital, Manchester, during the Michaelmas term commencing on Thursday, October 15th, when Mr. D. E. Hughes will deliver the first of a series of three lectures on the significance of urinary symptoms. On Thursday, November 5th, Mr. H. Platt will give the first of three lectures on the treatment of common fractures, with practical demonstrations. The lectures will be given on Thursdays at 4.15 p.m., tea will be served at 3.45. Further particulars can be obtained on application to Dr. Frank Holt Diggle, Honorary Secretary, Post Graduate Course, 26, St. John Street, Manchester.

A COURSE of lectures on pulmonary radiology with practical demonstrations will be given at Leysin (Switzerland), from November 3rd to 7th, by Dr. Jaquerod and Mr. Lauffenburger, radiologist of the Stat on Climatique de Leysin. Particulars as to the journey from Aigle to Leysin and information respecting accommodation in Leysin can be obtained from M. Lucien Emery, Administrateur, Grand Hotel, Leysin.

UNDER the auspices of the Society for the Study of Intoxication the eleventh Norman Kerr Memorial Lecture will be delivered by Dr. R. Herod, director of the International Bureau against Alcoholism, on October 13th, at 4 p.m., in the hall of the Medical Society of London, 11, Chandos Street, W.1. The subject will be "Alcoholism as an international problem."

A NEW series of weekly lectures at the Hospital for Sick Children, Great Ormond Street, W.C.1, commenced on Thursday last, when Mr. P. G. Doyle dealt with pharyngeal disease. On October 15th Mr. Fairbairn will lecture on spinal cases, and on October 22nd Dr. Frow will speak on acidosis. The lectures, which are free to medical practitioners, commence at 4 p.m.

At a meeting of the Society of Superintendents of Tuberculosis Institutions to be held at 122, Harley Street, on Monday, October 19th, at 3 p.m., papers will be read by Dr. J. W. Linnell on diagnosis and treatment and by Dr. F. R. Walters on needs and indications in pulmonary tuberculosis.

THE annual meeting of the British Dental Hospital will be held at the rooms of the British Dental Association, 23, Russell Square, W.C.1, on Thursday, October 15th, at 8 p.m. An address will be given by Dr. James Wheatley, County V.O.H. and School Medical Officer, Salop, on the subject of dental propaganda. The President, Sir Harry Baldwin, will take the chair.

At a meeting of the council of the Medical Defence Union, held on October 1st, Sir Herbert Waterhouse, F.R.C.S., consulting surgeon to Charing Cross Hospital was appointed President of the Union for the ensuing year, vice Mr. W. G. Spencer retired.

THE first number of the new monthly official organ of the Fellowship of Medicine was published on October 1st, and bears the title *The Post Graduate Medical Journal*. Besides detailed information about post-graduate classes, printed in a supplement, it contains introductory notes by Sir William Hale White and Sir Berkeley Moynihan, and the text of lectures delivered for the Fellowship this year by Sir Humphry Rolleston, on the medical aspects of gall stones, and by Dr. T. Watts Eden on the prevention of puerperal sepsis.

THE Fellowship of Medicine has arranged a series of free lectures on tuberculosis during October, November, and December in the lecture room of the Medical Society of London, 11, Chandos Street at 5.30 p.m. The first will be given on October 12th by Dr. J. S. Burrell, on tuberculosis from the physician's viewpoint. A two weeks' combined course in diseases of children with morning and afternoon sessions, will start on October 12th at the Paddington Green Children's Hospital, Victoria Hospital, and the Children's Clinic will participate. At St. Peter's Hospital a four weeks' course in urology will be held from October 19th to November 14th. From October 26th to November 20th the St. John's Hospital will hold a special course in dermatology. There will be a two weeks' intensive course in medicine, surgery, and the special departments at the Royal Northern Hospital.

Presidential Address ON OSTEOPATHY, CHIROPRACTIC, AND MEDICINE

DELIVERED BEFORE THE MEDICAL SOCIETY OF LONDON

BY

SIR H. J. WRIELAND, CBE, MS, FRCS,

SURGEON TO ST BARTHOLOMEW'S HOSPITAL

WHEN I was elected president of this society your secretary informed me that it was the custom for the incoming president to address you on some general subject in connexion with our profession. In discussing with him what might be a suitable subject, it was suggested that I should address you on "Osteopathy, Chiropractic and other Cults, and Medicine." This subject appealed to me to a certain extent, since during the past three or four years I have had so many inquiries from medical friends as to what was the exact nature of osteopathy and chiropractic, what advantages and results were to be gained from its employment, and what were its disadvantages and dangers.

In order to make myself as clear as possible I think it will be best for me to give you a commencement definitions of both osteopathy and chiropractic, and a statement of the principles, or so called principles, on which they are founded.

OSTEOPATHY

Osteopathy is a system of treating disease without drugs, and is based on the belief that all disease is caused by some part of the human mechanism being out of proper adjustment or alignment, as in the case of a misplaced bone, cartilage, or ligament, or in the case of adhesions or contractions of muscle resulting in unnatural pressure on, or obstruction to, a nerve, or a blood or lymph vessel. This definition is the one given in one of the latest American dictionaries and with slight variation that adopted by many of the osteopathic schools and practitioners. On investigation, however, one finds that the different practitioners of osteopathy have varying ideas as to what is exactly comprised within the meaning of the term and what limitations there are in the treatment. A later definition would appear to be more comprehensive and to include a use of the term "inhibition." According to the osteopaths, "inhibition" is the relief of pain, or spasm of the muscles, by the application of steady pressure.

The cult of osteopathy was founded by a Dr Andrew Taylor Still, a practitioner in the State of Missouri, in 1873. The first College of Osteopathy was opened in Kirksville, Missouri, in 1890, by Dr Still and a Dr William Smith, who was a medical graduate of Edinburgh.

According to Dr Still, all disease is due to, or dependent upon, a disturbance of the nerves or blood vessels of the different parts of the body, especially in connexion with the nerves coming out from the spinal column. A further and extended version of the theory of Dr Still was the assertion that the human body normally contains all materials which are necessary for healthy function, and if the circulation within the body is normal these elements will maintain health. The impairment of the circulation, which prevents the so-called elements or vital materials being properly supplied to the different parts and organs, is the cause of disease. The defective circulation, he says, is produced by the action of the vasomotor nerves. These nerves he assumes, are affected by the pressure from ligaments, bones, or muscles in the region of the spine, or by reflex irritation from a disturbance in the viscera or other parts of the body.

In short, then, osteopathy may be said to be a "therapeutic measure" or agent which is used for the treatment of all disease. The nature of this therapeutic measure is apparently a mechanical one, and consists really in making an alteration in position and relations by digital pressure or manual manipulation of the supposed diseased parts. In a narrower terminology osteopathy assumes that all diseases are due to an "osteopathic lesion," these lesions

being in connexion with the ligaments or joints of the spinal column.

The term "subluxation" has been used very extensively by practitioners of osteopathy to express a slight irregularity in position in the spinal column, its bones, ligaments, or muscles.

According to the osteopaths the abnormalities of the spinal column, which in their view give rise to disease, and which are called "osteopathic lesions," may or may not be shown by palpation, inspection, or x-ray investigation. Often, however, they are said to be characterized by localized areas of tenderness and muscular spasm. The osteopaths say that osteopathic lesions ought to be found in connexion with the spinal column, its ligaments, muscles, and joints, in all diseases. The site of the lesion varies according to the locality of the disease, the nature of the affection apparently not having any influence on the exact site or locality of the supposed "lesion." According to *Osteopathic Pathology*, if the stomach is the site of an ulcer or tumour, or is displaced into some abnormal position, the site of the osteopathic lesion in the spinal column would be the same, hence the osteopathic treatment or removal of the osteopathic lesion would be the same. Similarly, according to osteopathic pathology, cancer of the kidney, nephritis, enlargement of the kidney, or tuberculous of the organ would all show a similar osteopathic lesion in a definite portion of the spine, different from that effected in diseases and affections of the stomach.

The treatment adopted by the osteopath is by manipulation to correct the so-called deformity, or osteopathic lesion, to bring into proper apposition displaced bony surfaces, to relax muscular spasms, and to eradicate tender points.

As regards acute infectious diseases, the osteopath claims that circulation of the blood along the courses of the nerves and the blood vessels is interfered with, and therefore portions of the human body are unable to withstand the onslaught of the disease. He asserts, can be cured by "replacement of subluxation." If that is necessary to enable the human organs to withstand any of these diseases.

CHIROPRACTIC

Chiropractic has been defined as the philosophical science and art of things natural, and a system of adjusting the subluxated vertebrae of the spinal column by hand for the restoration of health. This cult was "discovered" by a layman, D. D. Palmer, in 1895, who founded the Palmer School of Chiropractic in 1895 at Devonport, Iowa, U.S.A. This has been continued by him and his son since then.

The theory of chiropractic says that all disease is the result of pressure upon nerves as they emerge from the spinal canal. This pressure is assumed to be caused by an abnormal position of the vertebrae. According to Palmer, diagnosis is not necessary for the treatment of disease. All that is requisite is to relieve pressure on nerve roots. This having been done, whatever the nature of the disease, health will follow. A more recent definition of chiropractic (Gk *cheir*, hand, and *praxis* to do) is "a system of adjustment consisting of palpation of the spinal column to ascertain vertebral subluxation, followed by the adjustment of them by hand, in order to relieve pressure upon the nerves at the intervertebral foramina so that nerve force may flow freely from the brain to the rest of the body."

The osteopath and chiropractor each states that he can cure practically all diseases, injuries, or malformations by manipulating the spinal column and putting displaced vertebrae in correct positions after what he calls "subluxations" have occurred. Diseased conditions of the eye and the ear which give rise to either blindness or deafness are treated by them in a similar manner, although the nerves of these organs are not given off from the spinal cord and do not pass through the spinal canal and its foramina.

In the United States of America "investigators" have been treated in osteopathic and chiropractic schools, and they have had their spinal columns examined by x-rays both before and after osteopathic or chiropractic treatment. No change has been apparent to trained x-ray

experts, although the osteopath or the chiropractor has claimed that he has first diagnosed and then reduced subluxations of the vertebrae.

From osteopathy and chiropractic many other cults have sprung, and it is not necessary for me to say much concerning them. About one, however, I might say a few words, and that is niroprathy. The practitioner of this cult states that the basal centres of life are all located in the medulla oblongata, or basal portion of the brain. The nearest portion of the surface of the body to the medulla oblongata is the nape of the neck. Therefore, in order to apply manipulations for the cure of disease, these are given to the nape of the neck.

I was interested to read a prospectus of one of the chiropractic schools, in which it is stated that chiropractic "is a science of adjusting the cause of disease by relieving by hand misplacements of the twenty-four movable vertebrae of the spinal column or disalignment of the sacro-iliac joints, and so relieving pressure on the nerves which radiate from the spine to the various parts of the body." In order to do this no medicines are prescribed, no surgical instruments are necessary—only thumb pressure and free rubbing with the heel of the fist. Everyone who can read and write can soon be taught to become proficient in the science of chiropractic. In order to be successful, however, it is necessary for the practitioners to deny and abuse regular medical practitioners, drugs, and other forms of therapeutic treatment. In order to be successful it is necessary that free advertisement should be practised, since a considerable proportion of the populace are much more prone to believe extravagant assertions contained in displayed advertisements than the wise counsels given to them by their regular medical practitioners.

It will thus be seen that both osteopathy and chiropractic first of all assume as basal facts conditions which are absolutely untenable scientifically. The osteopath thinks that all disease is caused by interference with the blood and nerve supply, and that relief of this condition by manipulation will cure all disease. Chiropractic assumes that all disease is dependent upon pressure on one or other of the spinal nerves, and that relief of this pressure will cure disease. Niroprathy assumes that all disease is due to pressure in connection with the medulla oblongata, and that manipulation of the nape of the neck for the reduction of this pressure will cure disease.

From these definitions it will be seen that all these cults base their theory and practice on a primary dogma which is untrue. It is interesting to note in some of the prospectuses in the United States that the chiropractor constantly asserts that there is no necessity for him to have any proprietary qualifications beyond those of his so-called chiropractic college. He diagnoses and repudiates the diagnosis of disease and states that a knowledge of bacteriology, pathology, and chemistry is not necessary. All that is necessary for the osteopath or chiropractor in the treatment of his patients is to apply his criminal principle in all cases without examination and without diagnosis.

In the United States of America, which is the primary home of osteopathy, chiropractic, and all the derivative cults, there has sprung up within the last twenty years a considerable number of irregular medical schools, or self-called colleges, teaching the principles and practice of their cult, and labelling the students attending them with their so-called "degrees." In the main it would appear that these schools have taken the place of those low-grade medical schools which had to close their doors owing to the action of the American Medical Association in grading the medical schools and colleges, and the general enforcement of certain standards of curriculum and equipment. These schools apparently in all instances are proprietary, and are run much more as regards private gain for the proprietor than for the provision of well qualified practitioners of the healing art for the community.

COURSES OF INSTRUCTION

Apparently the only essential elementary education which is insisted upon by most of the osteopathic and chiropractic schools is ability to read and write. No examina-

tion in preliminary education and no attendance at a high school is required. The duration of the course in most of these colleges appears to be three years. These three years, however, are stated to be of six months each, and it is the usual practice for them to be continuous. Thus a student of an osteopathic or chiropractic school or college may attend and complete the whole of his course in eighteen months. A study of the prospectuses of many of these schools shows that very little instruction is given in the basal sciences, such as chemistry, physics, biology, and physiology, and what is given is of didactic character. Laboratory instruction in the modern acceptance of the term does not seem to exist. In most of the schools diagnosis of disease is not considered necessary, and clinical teaching as practised in an ordinary medical education does not exist, no hospital clinical facilities being available.

After the "three years" (course of instruction) graduation takes place and degrees are conferred. The osteopathic colleges confer the degree of D O (Doctor of Osteopathy), and the Chiropractic College D C (Doctor of Chiropractic) and Ph C (Philosopher of Chiropractic).

It would appear that the examinations are purely formal, and all candidates who have paid the fees and may have attended the courses of instruction are given the degrees. At one of the largest colleges, which professes to have over 3,000 students in attendance, there is apparently one examiner for the graduation of students. Concerning the examinations, one "candidate" who was an "investigator" of these cults deliberately answered all the questions wrongly. This did not matter—he passed and was granted his degree.

At one of the largest schools of chiropractic in the United States in the course of instruction "philosophy" is given the first and most prominent place. Anatomy is taught by a lecturer who apparently has never gone through a regular course of dissection of the human body, and has no recognized medical diploma or degree. The teaching is entirely didactic, and no dissection of the human body is practised, but on occasions dogs are used for dissection. Obstetrics and gynaecology are taught without in patients in a hospital. One of the most prominent courses of instruction in the curriculum is what is called "salesmanship." In this course personality, personal magnetism, and psychology, various forms of advertising, selling the patient, and selling the services of the practitioner, are given, much more time and prominence being given to these subjects than to study of diseased conditions. As regards infectious and contagious diseases, these he treats in the same way as all others. He states that there is no necessity to isolate. Consequently he is prone to carry scarlet fever, diphtheria, etc., broadcast.

As an explanation of the effects of osteopathy and its use as a therapeutic agent, the osteopath states that "osteopathy is something which cannot be learnt from books but only by personal instruction from a previously qualified osteopath."

The osteopath or chiropractor during the student curriculum is taught the best method of advertising and selling his services, so that when fully fledged, and having received his degree, he may at once be in a good position to attract practice.

Recruits, or students, for the colleges apparently are obtained to a great extent by allowing advertisements, in which a would-be osteopath or chiropractor is offered inducements which suggest earning large incomes and becoming a member of a respectable and valued profession. A considerable number of the students appear to be drawn from the poorly educated classes, and to have had little general education. As an experiment a friend of mine in one of the United States requested his secretary to write to a large chiropractic school, saying that her occupation was that of a chauffeur. In reply she received an invitation to join the school without delay, and all the inducements just mentioned were offered to her.

The methods of practice by osteopaths and chiropractors would appear in the main to be similar. Both assume the existence of subluxations and displacements of the spinal column located in various levels according to the supposed site of the disease. The chiropractor generally takes with

him, if he visits a patient, what is known as a "chiropractor's table." This is a long table padded at each end and with an interruption in the middle. The upper portion of the chest of the patient when undergoing treatment rests on the upper padded part, and the pelvis and limbs on the lower. The treatment in the main consists of application of pressure and manipulations at the supposed site of the osteopathic or chiropractic lesion. The treatment appears to be the same for all diseases, and consists of applying what is described as the chiropractic thrust or thump. This is done by first of all localizing the exact spot, or supposed site, of the lesion, such as the apex of the spine of a vertebra, then the pisiform bone of the right hand of the osteopath or chiropractor is placed on this spot, the wrist of the right hand is then grasped with the left hand, and a firm sudden pressure applied. The force and the method of applying this particular thrust varies with the different practitioners. In some cases I have been informed that the operator immediately after he has given a thrust or thump simultaneously makes a chiding noise with his tongue and explains to the patient that the displacement has been reduced. It is usual for the osteopath and chiropractor to recommend that a regular course of treatment should be taken by the patient.

DANGERS OF THE PRACTICE OF OSTEOPATHY AND CHIROPRACTIC

Since most of the practitioners of osteopathy and chiropractic have no general knowledge of the nature and diagnosis of disease, patients who are suffering from serious affections are very liable to be severely damaged by an osteopath or chiropractor. As illustrations I might mention

1 *Appendicitis with Abscess*—Many cases are on record where an osteopath or chiropractor has been called in to treat a patient for abdominal pain, the cause of which pain was appendicitis with abscess. "Treatment" has been applied, the abscess has been ruptured, and the patient has died from acute peritonitis. In connection with the treatment of appendicitis by chiropractic methods one chiropractor in Brooklyn states that when a chiropractor is led to suspect appendicitis—"which disease," he asserts, is due to displacement to the left of the second lumbar vertebra, this displacement of the second lumbar vertebra in between the first above and the second below resulting in a pinching or nipping of the nerves on the right side between the vertebrae—"replacement" of the subluxated second lumbar vertebra by correct manipulation by the hands relieves the nipped or pinched nerves, and in most cases causes a resolution of the inflamed and diseased appendix and recovery." This is a typical example of the so-called pathology which is given by the osteopath and chiropractor in his explanation of disease.

2 *Malignant Disease*—Many cases are on record where the manipulations of an osteopath or chiropractor have caused acute dissemination of carcinoma and sarcoma. Some years ago I had an example of a similar kind. The patient was referred to me at St. Bartholomew's Hospital. He stated that he had a displaced cartilage of the knee. For this he had consulted and had been treated by one of the well known osteopaths or bonesetters in this country. Manipulations were carried out on numerous occasions over a period of nearly a year. The patient's funds having gone, and being unable to pay for further "treatment" and manipulations, he consulted a private doctor, and was sent to me at the hospital. On examination he was found to have a large anconatous growth in the upper end of the tibia, which necessitated amputation of the limb. A section of the amputated limb showing the growth is in the museum of St. Bartholomew's Hospital.

3 *Tuberculous Disease of the Joints*—I have seen several cases of tuberculous disease of the joints which have been treated by such serious damage has been done by and movements. Many other surgeons to my knowledge have had similar experiences.

4 *Acute Infectious Diseases*—In the United States many cases of acute infectious diseases, such as diphtheria, smallpox, scarlatina, and so on, have been treated by chiropractors, and epidemics of disease established owing to the chiropractor carrying the infection broadcast.

THERAPEUTIC VALUE OF OSTEOPATHY AND CHIROPRACTIC

As regards the therapeutic value of the work of the osteopath and chiropractor (manipulations of the spinal column and so-called replacement of subluxated vertebrae), it can be stated that these manipulations in some diseases and abnormal conditions do no harm, but in the majority of diseased and abnormal conditions considerable harm will be done, and in some cases irreparable injury.

Concerning the advantages of osteopathy and chiropractic as a therapeutic measure, it appears to have given considerable relief to a number of patients suffering from obscure and painful affections of the dorsal region of the trunk. Some of these cures have probably been due to suggestion, others to the direct results of manipulations, and breaking down or separation of adhesions between muscles or nerves and adjacent tissues by fibrous tissue.

It is a curious fact that the ordinary medical man has a wholesome horror of using considerable force for the breaking down of adhesions, owing to the fear of doing serious injury, the osteopath, chiropractor, or bonesetter has no such fear, and uses considerable force, and effects in many instances what the medical man was afraid to do. During the latter period of the war when I had the inspection of the surgical military hospitals in London I found this was a marked feature in military surgery, consequently my time was considerably occupied in dealing with cases of adhesions of one kind and another.

In connection with chiropractic, Dr. F. H. Albce says that in all his experience, and in all his examinations of the spinal column, and in all the operations which he has performed, he has never discovered any foundation for the chiropractic theory. The spinal foramina through which the nerves pass are too large to permit any pressure except in cases of dislocation of the vertebrae, and then paresis or paralysis results. He states that in his opinion chiropractic is a menace to the public at large. In the first place it entirely ignores bacteriology and leaves doors wide open to the spread of contagion. He states that propaganda leads people to throw their money away on false promises of health and tends in some cases to delay proper treatment until it is too late.

POSITION OF OSTEOPATHS AND CHIROPRACTORS IN THIS COUNTRY

Unless possessing a medical qualification from some recognized medical licensing body osteopaths and chiropractors cannot be registered by the General Medical Council, and can only carry on their practices here as unregistered and unqualified practitioners. They cannot sign death certificates, they cannot sue for fees for services rendered, they cannot obtain an authorization for dangerous drugs, and they are liable to prosecution for malpractice.

It would appear that the object of osteopaths and chiropractors is to obtain legalization and registration by Act of Parliament. It would seem that they desire to be recognized as drugless healers with limitations as regards practice. On the face of it recognition might appear to be easy, but it has been found by experience in some of the States in America where such licensing has been established that limited registration for medical practitioners for the treatment of disease is very unsatisfactory. There is always the question as regards diagnosis and to what extent manipulative methods may be employed. I have often been asked what is the position of the General Medical Council and the qualifying bodies in connection with the practice of osteopathy and chiropractic. My reply has been that our medical practice laws ought to be amended so as to place all practitioners of the healing art on the same educational level.

There is no doubt that the so-called success in practice of the osteopath and the chiropractor is largely due to the following facts:

1 *That patients look upon medical matters and their diseases as being allied to mystery.* This is a survival, in all probability of the days when the practices of the priest and the doctor were combined.

2 *The public is always dissatisfied with a doubtful diagnosis given by a physician or surgeon, and of his inability to explain the nature of a disease in a few words, and also cure it with a definite remedy.* It is desirous of having given to

it a simple statement of why the patient becomes diseased and how he may be cured. It does not matter how improbable or how untrue an explanation of this kind is, provided there is a small amount of plausibility. Consequently large numbers of educated and intelligent people are imposed upon by the superficial so-called "explanation" of the osteopath and chiropractor. Thus it is very easy for the chiropractor to assert that every physical process of the human frame is due to something passing along the nerves, and that the important nerves lie in the spinal column, from whence they go to their destination. Subluxations or dislocations of the spine cause pressure by the bone on these nerves, interference with the passage along the nerves of the vital force to the different parts of the body, and so cause every variety of disease or deformity. To the public very often such an explanation as this is thought to be sufficient even as regards diseases of the eye and ear, although the nerves of these organs do not pass through the spinal column. As regards diseases due to micro-organisms, he explains that infection only proceeds when displacements of the spinal column have occurred, and the vital force is prevented from going to the distant parts of the body, and hence the germs are then able to cause the various diseases, owing to a diminished supply of "vital force" in these parts.

3 Ability to advertise. Individuals who are seriously ill, or suffering from an incurable disease, very often grow desperate in searching for a cure, their mental condition becomes affected, and their judgement weakened, so much so that they readily fall into the clutches of the osteopath, chiropractor, the charlatan, the quack, and pretended healer after reading some misleading or lying advertisement. The plausible osteopath or chiropractor says that physical interference with the circulation and passage of vital force along the nerves is the cause of disease, and when the interference is sufficiently severe is the disease itself. These interferences, he explains to the patient, take place in the spinal column, and he asserts that the removal of these pressures is the removal of the cause of disease, that this is essentially the work of the chiropractor, that his highly cultivated sense of touch enables him to appreciate these interferences by palpation, that he readjusts the bones and relieves pressure, and so restores harmony between the brain and the tissues and organs of the body. He also promises the patient a cure if he will go through a course of treatment. A favourite device which is made use of by many osteopaths and chiropractors when explaining the cause of disease to patients, prospective or otherwise, is to take two dorsal or lumbar vertebrae, articulate them together, place in one intervertebral foramen a piece of rubber tubing sufficiently large to fill the aperture, and then to make a slight displacement of the bodies of the two vertebrae. This displacement, of course, at once diminishes the calibre of the tube, and according to the osteopath or chiropractor diminishes the flow of blood or vital force along the nerve emerging from the foramen, and so interferes with the nutrition of the parts or organs supplied by the nerve, thus causing disease or a tendency to disease. The osteopath or chiropractor giving such an explanation omits to mention that the nerve does not fill more than one-half of the aperture, that it is surrounded by a large quantity of fatty and fibrous tissue, and that to produce the amount of displacement necessary to press on the nerve in the manner mentioned would require a traction force of more than half a ton. Such, however, is the ignorance and gullibility of the average member of the community on matters medical that he is readily imposed upon by the plausibility of the osteopath or chiropractor, and believes in his statements.

According to recent information it would appear that considerable numbers of so-called graduates of the osteopathic and chiropractic colleges have been turned out in the United States. The majority of these would appear to be individuals who have had very little preliminary education, no basal scientific training, and no practical knowledge of anatomy, physiology or applied chemistry, and no experience in diagnosis of disease in living patients. Many of these have received their so-called diplomas after a course of study by correspondence, others again, after a short stay in one of the schools above mentioned. Many of

these come to this country and establish practice, and by blatant advertisement establish their cult.

THE DUTY OF THE STATE

The increase in the number of osteopaths, chiropractors, and other cultists in this country is considerable. As they claim to be licensed to practise the art of healing, it appears to me absolutely essential that there should be further regulation by the State of all those who take into their hands the responsibilities of the lives of others, and that everyone who is licensed to practise as a medical practitioner in any form should be placed under the same requirements of knowledge and experience. Such regulation and licensing by the State is due, not only to the members of the medical profession, but also to the members of the population as a whole. The progress of the community depends to a great extent on the health of the people. The State, therefore, ought to take a strong stand in protecting the health and preserving the life of its various citizens.

According to all the known facts of pathology and the causes of disease, it is essential before making attempts to treat a patient that the practitioner of medicine should be able first of all to make a diagnosis, and recognize whether the patient is suffering from a disease or not, and, if not, he cannot be in a position to treat intelligently and look after a patient by any method. In addition, it is necessary that he must have a knowledge of the different therapeutic measures and materials which are used in the treatment of disease, so that each individual patient may be treated in the proper manner.

Concerning the practice of medicine, it is maintained by some that an individual's disease is his own concern, and that he has a perfect right to employ anyone, trained or otherwise, to treat him. There is no doubt that it is a dangerous fraud for an individual to represent himself as qualified to treat disease and care for the sick by claiming the possession of knowledge and experience in treating disease which he does not possess. This means that no individual has a right to commit a fraud. It ought to be the duty of the State to prevent the perpetration of dangerous frauds, especially when they concern, not merely the individual who is defrauded, but other members of the community.

It appears to me that it is essential for the good of the community that all individuals licensed to treat the sick members of the community should have received the same basal education, and should have passed through practical courses qualifying them to obtain diplomas or degrees. At the present time the minimum curriculum in this country is a five years course of study after having passed a preliminary examination in general knowledge, and a pre-registration examination in elementary chemistry and elementary physics.

It has been urged by the osteopaths and chiropractors that they ought to be treated in the same manner as dentists under the new Dentists Act and receive a partial licence to practise as osteopaths and chiropractors. The practice of osteopathy and chiropractic cannot be compared with that of dentistry. The dentist first diagnoses and then treats diseased teeth only, he does not treat other diseases, and does not assume that all diseases in the human frame are dependent on the diseased condition of the teeth. If the methods of the osteopath and chiropractor were followed by the dentist, then the dentist ought to make a claim of this kind, saying "that every diseased and deformed condition of a patient is due to the poisonous chemical substances produced in decaying teeth being absorbed into the body and conveyed by the blood vessels to different parts of the body and there causing disease." Such a claim by the dentist would have much more right to recognition as a pathological fact than the claim by the osteopaths or chiropractors that all diseases are due to misplacements and subluxation of the spinal column involving either the spinal nerve or the blood vessels in connexion with them. It seems to me, therefore, that this contention of the osteopath or chiropractor ought not to be seriously considered and certainly not allowed by our Legislature. The only satisfactory method of protecting the community from fraud in connexion with disease is to ensure that every individual who treats disease shall be licensed only after having passed

through a satisfactory educational career. In these circumstances I maintain that even osteopaths, chiropractors, or other cultists who wish to practise in this country ought to go through similar courses of instruction before being licensed to practise the healing art.

In this connexion it appears to me that instead of the Legislature making possible the licensing of osteopaths in a very limited form of practice, the Medical Acts ought to be so strengthened that it would not be possible for the community to be treated by them or any other unqualified charlatan or quack. From a practical point of view it appears to me that the members of the community ought to be educated as to the real position and the nature of the practice of osteopaths, chiropractors, and other cultists. This might be effected by making instruction in general and personal hygiene compulsory in our schools. A small textbook on the subject should be available, and it ought not to be impossible to arrange that a course of instruction on this subject should be given in all our elementary schools. The Legislature, through its Education Acts and by its medical officers, makes periodical examinations of school children as regards their general health, teeth, mentality, and so on. If this is possible surely it would be an easy matter to arrange that a course of instruction such as outlined above should be given by its medical officers.

In a similar manner a course of instruction should be given in our secondary and public schools, and an appropriate textbook provided. By means of instruction of this kind at an early stage of an individual's career he might be taught to have a definite and correct opinion as regards disease and the proper methods of its treatment. Some people have advocated that the medical profession should undertake a scheme of propaganda by film, lecture, and otherwise for the education of the public and their protection from unqualified medical practitioners. This might be very desirable, but it does not appear to me that it ought to be carried out necessarily by some organization or other of the medical profession, since this profession would lay itself open to the criticism that it is a trust which is trying to protect itself. It should be done, if considered advisable, either by the General Medical Council in a manner similar to that carried out for the education of the community in dentistry by the Dental Board, or by the Ministry of Health. Perhaps the latter body is the more correct one for this purpose, since the General Medical Council is primarily concerned with education and registration, and unless provision is made for the purpose does not possess the necessary funds.

A Lecture

OF

SOME INTESTINAL DISORDERS OF INFANCY*

BY

HUGH T. ASHBY, B.A., M.D., F.R.C.P.,

PHYSICIAN TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL, ETC.

No infant, whether fed at the breast or with artificial food, escapes having indigestion in one form or another. We do not have to go far to explain this. During infancy the stomach and intestines are worked at a very high pressure to digest the food required for the infant's maintenance and growth. Any overtaxing of its powers is likely to be followed by disturbed function. The commonest causes of indigestion in infancy are practically those of adults—for example, more food is taken than can be digested, or an improper food is given, which cannot be digested without the child getting colic and flatulence. There is no fact more clearly established than the great importance to the health and life of infants that they should be breast-fed for at least six months. If the infant is so fed for this length of time, even in the poorest surroundings and poverty, it will stand a very good chance

of living. The baby will escape the many pitfalls and dangers which lurk behind food out of a bottle.

It is the duty of every medical man and woman to persuade mothers to breast-feed their infants, and often a little perseverance on the part of the mother will enable her to do this, even in cases where it appears at first almost impossible. Directly a baby is weaned, especially in the first few months, difficulties are liable to arise, such as what to feed it on, how to prepare the food, the quantity to give, and so on. Even one or two breast-feeds a day, with the rest of the feeds of cow's milk, are a great help.

When the time for weaning comes, about the eighth to ninth month, it should be done by gradually replacing the feeds from the breast with the artificial food chosen. It is always a good thing to give one feed a day of artificial food from a bottle at about the fourth or fifth month, so that the infant becomes accustomed to the bottle and weaning can take place easily when it becomes necessary. This also gives the mother greater freedom. It is often a struggle to wean a baby all at once, and the one bottle early on enables weaning to be done at any time. It is seldom that breast-feeding is inadvisable. A mother with phthisis should not suckle her baby, for the reason that the mother will very readily infect her child, and it is injurious to her own health. Again, the mother may have wasted so much during pregnancy that her health will not stand the strain. There are practically no other reasons for the mother not trying to feed her infant.

Milk

There is perhaps no single factor in connexion with infant mortality so important and so full of pitfalls as the supply of milk. The general public know little about milk, and they are quite content as long as the milk is delivered regularly and is not sour. The quality of milk supplied to most large towns is not good, and until this is improved we cannot reduce infant mortality to what it should be. The infant does not know the possible results of the food it is getting and can only express disapproval by its cries, vomiting, and diarrhoea. It is common for one food after another to be tried with bad results, and our methods of feeding infants in the past have been too haphazard. Cow's milk, when pure, is an ideal food, but it is of all foods the most difficult to preserve and to handle successfully. To ensure artificial feeding being a success the mother must be taught how to modify it so that the infant can take it and digest it well. Cow's milk can be modified in so many different ways that practically every infant can take it and thrive. Cow's milk has an advantage over all patent foods in that it can be made to resemble human milk closely.

Many proprietary foods have the disadvantage of an excess of starch, and infants fed on them may apparently thrive and become fat, but they are often by no means healthy. It is not the large, fat babies which are the healthiest and the ones to stand best the strain of a severe illness. In the majority of cases where cow's milk has been tried and found to fail it has not been given in the proper quantity and strength. Foreign countries are more strict than we are in the use of proprietary foods for infants. Such foods need careful preparation, and it is a common fault to prepare them too weak.

In some cases the wasting or failure to gain in weight is the fault of the infant, and not of the food which it is having. Certain infants, although fed well, and even breast-fed, do not thrive, and this is sometimes seen in a family when each successive infant dies at the age of 3 or 4 months or sooner.

As a result of faulty feeding, an infant suffers from malnutrition, which is a comprehensive term covering a low condition of health and a lack of resistance to disease. Insufficiency of food is probably of less importance than unsuitability. Irregularity of feeding is often the cause of wasting, as it produces indigestion. It is common to find a wasting infant fed whenever it cries. Irregularity is a common cause of indigestion in adults, but the digestion of infants is even more easily upset. Feeds too large for the age are a common mistake and not recognized at first,

* British Medical Association Lecture delivered before the Border Counties Branch June 5th 1925.

for the infant may do well and have big gains in weight each week. After a time there is an upset in the digestion and the weight becomes stationary and then begins to fall. Such cases are very difficult to treat. The diluents used in the modification of cow's milk are sometimes at fault, it is common to make barley water far too thick, with the idea that the food will be stronger and hence the infant will gain the quicker. Plain water as a diluent has the great advantage that it takes no making, and there is not so much likelihood of mistakes. Lately, we have had much success with malt stock (Mottershead, Manchester). This is an active malt preparation and made with milk. It is a copy of the "malt suppe" used abroad very largely before the war. It must always be remembered that the strength of a food and the amount given at each feed should be according to the infant's weight and not according to its age.

Flatulence and Colic

We often see a baby who according to the mother—and, I may add, the father too—is always crying. This in most instances means colic with a certain amount of flatulence or wind. Colic should never be regarded as a trivial symptom, it is often most difficult to alleviate and it causes much trouble to the parents. The baby is often only quiet when it is asleep—the rest of the day and night it is crying. It keeps the neighbours awake and is a perfect nuisance. Such a baby generally fails to gain weight, for it is the placid one that does the best. Moreover, in bad cases of colic, convulsions are liable to supervene. The main causes of colic are flatulence and undigested food, with constipation. Taking flatulence first, it is remarkable how much distress and disturbance it can cause. It often leads to vomiting after the feeds, as the wind bungs the food up with it, this leads to wasting from want of food, and so intensifies the crying from hunger. Hiccups is also a common accompaniment of flatulence.

Causes of Colic

An investigation of the diet will generally reveal the cause. First, too large feeds at too frequent intervals are being given. These large feeds distend the stomach and dilute the gastric juices. It is always good to calculate how much food an infant is having in the twenty-four hours. Hardly any infant—no matter how heavy—needs more than 40 oz of food in twenty-four hours. Personally, I am generally in favour of three-hourly rather than four-hourly feeds. Another common cause is too much carbohydrate in the food—either too much sugar is added to each feed or a potent food containing much starch is given to the child. An ordinary cow's milk feed needs about one teaspoonful of cane sugar added to each feed, and there is no advantage to be gained by using sugar of milk. It is often good to change the kind of sugar used in order to vary the taste of the feed. It is not surprising that a baby will get tired of a certain food which is given day after day.

Treatment

A fairly weak feed should be started with and then gradually strengthened. Always feed according to the weight not according to the age. It will need a good deal of perseverance to get the baby right. Pick the baby up after a feed to let the wind come up. If the colic is at all severe, peptonized milk is likely to suit well, for the digestion of the curd is done for the baby.

A mixture such as sod bicarb gr 3, spt amm atomat min 12, tr card co min 3, syr zingib min 5, aq errui ad dr 1 four times a day before a feed may help a good deal. The bowels must be kept well open and an aperient given regularly each day, and not when the child is constipated. It is no use waiting to give the aperient when the child is constipated—the need is to anticipate the event. Much constipation in infancy and childhood could be prevented by good training from the earliest days. The same applies to older children, especially those attending school. It is often the custom for the boy or girl to rush off to school directly after breakfast. Time should always be made for going to the closet before school. Another thing to remember is that it is no use sending a child to the closet to stay there for an unlimited time. All he does is to twiddle his thumbs or read a book.

Intussusception

Before leaving the subject of colic, the possible presence of intussusception must be borne in mind. Any infant who suddenly begins to kick and scream without obvious cause may quite likely be starting with an intussusception. Such an infant soon begins to vomit and to strain as if it wanted to pass a stool, but nothing escapes except a little blood and mucus. On examining the abdomen with a warm hand it is usually found more or less soft, and the tumour may sometimes be felt. In very fat infants it may be quite impossible to detect the tumour. The rectum should not be carefully explored with the finger, and the apex of the tumour may be felt, and the exploring finger on being withdrawn may be streaked with blood. The position of the tumour varies, of course, according to the length of the included gut and according to how long the intussusception has lasted.

Many cases are very difficult to diagnose especially in the early stages, and what I think often happens is that an infant starts with an intussusception which unfolds itself on its own. It is impossible to say so quite definitely, but we see patients whom we strongly suspect of having an intussusception but who suddenly get well and stop the crying from pain and the straining.

The large majority of cases occur under the age of 1 year, and a common age is 6 months. Breast and artificially fed infants suffer alike, and it is often the big fat babies which get it.

Treatment consists in performing a laparotomy at the earliest possible moment, and if this is done in the first twenty-four hours all should go well. The outlook becomes increasingly serious the longer it is left, and it is nearly hopeless after the fourth day, for the reason that the gut is likely to be gangrenous. Once an intussusception takes place no medical treatment is of any avail: the child must be operated upon and the gut unfolded.

Diarrhoea in Infants

Diarrhoea is perhaps responsible for more deaths than any other disease during the first year of life. Thus used to be specially the case during a hot dry summer. However, by improved sanitation and by the prevention of flies, it is now much ameliorated.

It is the wearily babies, fed on artificial food, that suffer from enteritis. Of these foods condensed milk is perhaps the worst, for it contains so much sugar, and its stickiness attracts flies to infect it. Vomiting may accompany the diarrhoea, and makes the trouble worse. Such an infant wastes very quickly and goes downhill: the eyes get that peculiar sunken look, the limbs become flabby, and the skin harsh and dry. The wasting is produced by the great loss of fluid, and the infant, as it were, dries up. All young children stand loss of fluid very badly, and it is a mistake to withhold water from a child at any time.

A purge should be given at once to clear the infecting microbes away. Castor oil serves the double purpose of producing a good clearing out and then constipating, which is exactly what we want. If castor oil cannot be tolerated on account of vomiting give half a grain of calomel instead. All milk should be stopped. This is perhaps the most important of all. Water with a little sugar may be given, and the infant cannot have too much. It should be given every hour by the mouth, and the infant will take this well, as it is thirsty. If there is vomiting, fluid must be given, as saline solution, by the rectum every four to six hours. Salines are easy to give by the rectum in children, and a mother can be taught to carry this out. In severe cases it may be necessary to give the saline solution subcutaneously or through the anterior fontanelle into the superior longitudinal sinus. Albumin water is being given up, as it contains little food, and any good that it does is most probably due to the water. Often we have to make a pretence of giving some food in deference to the parents, in these cases however may be recommended. As soon as the diarrhoea is abating I would suggest giving a weak dried milk feed for a short time before starting with the cow's milk.

Sequelae

An infant may be left with a weak digestion and fall into a state of marasmus. Bronchitis is a very common accompaniment, and such patients must always be kept very warm. After prolonged enteritis, swelling of the backs of the hands and dorsum of the feet is common. This is toxic oedema, and has nothing to do with kidney disease. Drugs form a minor part of the treatment. Bismuth in some form does, however, help to diminish the number of motions, and small doses of opium at the proper time. Never give opium at the onset or if the infant is collapsed. Opium is however, useful when the large bowel is affected and there is excessive peristalsis going on.

Pyloric Stenosis in Infancy

A clear understanding of the condition and the recognition of the importance of early diagnosis, and so treatment, is most important. I am quite sure that if pyloric stenosis in infants could be recognized early many lives would be saved. It is a more common condition than is usually thought to be the case. By pyloric stenosis we mean a great hypertrophy of the circular and longitudinal muscles which control the passage of food from the stomach to the duodenum. The muscle here becomes enormously thickened and hypertrophied so as to block the pyloric canal. The consequence of the block is that the stomach wall also increases in thickness as it tries to force food through the tight pylorus. As the food cannot get through the pylorus it is vomited forcibly. In the great majority, the infant is a boy. Many cases occur in the first-born, there is a special liability for any first-born infant to have an abnormality.

The symptoms do not appear till the infant is at least two weeks old, and the commonest time for the vomiting to start is at the age of two to four weeks. It is forcible and projectile in character and large in amount, for more than one feed may be brought up at a time. Constipation is marked, for little passes through the pylorus. The wasting is rapid and progressive, as little food is retained. The infant is greedy for the feeds, as it is hungry. This is quite unlike ordinary dyspepsia.

Waves of peristalsis may be seen passing across the abdomen, due to contractions of the stomach. They are best seen while the infant is having a feed or soon after. This peristalsis may be seen in other conditions besides pyloric stenosis, but it is especially well marked in it. The pylorus may be felt under the right rectus muscle, about an inch above the umbilicus. If the tumour is not felt, this fact should not disturb us as the detection of the tumour is often quite impossible. I am quite convinced that so soon as the condition is diagnosed surgical intervention alone will give the best results. Although medical treatment has undoubtedly been successful in a number of cases, much valuable time may be lost, and the infant will be, in consequence, less able to stand the operation. The best operation is that devised by Ramstedt. It consists in a transperitoneal incision of the hypertrophied pyloric ring leaving the mucous membrane intact, thereby restoring the continuity of the alimentary canal. The mortality is now being very much reduced by this method, and it should be only about 10 to 20 per cent., or even less.

Breast-feeding is a great help in the after-care of these cases, and the mother should be carefully looked after to see that her milk does not cease during the short operation period. If the infant survives, there is no disability left in the future.

PARTIAL INTESTINAL OBSTRUCTION IN A CHILD DUE TO POST-RECTAL TERATOMA

BY

A. ERNEST SAWDAY, M.B., B.S. LOND.,
MRCS. LRCP,

SURGEON TO THE DERBYSHIRE HOSPITAL FOR SICK CHILDREN.

This case is interesting on account, not only of the rarity of the tumour described, but also of the condition of bowel obstruction resulting from it.

Bland Sutton¹ states that post-rectal teratomas are very rare. There is a specimen in the Middlesex Hospital museum containing hair, grease, and a tooth. The origin

of these tumours is obscure. They are probably the result of incomplete dichotomy at an early stage. Keen removed a tumour connected with the skin by a cartilaginous tract resembling a tether. Some post-rectal tumours have been described communicating with the sacral dura mater and resembling spinal bifida sacs.

D. C., a boy aged 4 years and 5 months, was sent to the Derbyshire Children's Hospital by Dr. G. S. Sims of Derby on February 5th, 1925. The mother stated that the boy had been very constipated for a few weeks, and that a fortnight previously his abdomen had suddenly swelled up. On close questioning she admitted that the child's bowels had never been regularly moved since birth. There had been no vomiting nor any failure of appetite.

The boy was somewhat undernourished. The abdomen was enormously distended and resonant all over. A hard mass could just be felt on deep palpation above the pubes. Peristalsis was easily seen. The liver dullness was normal, the spleen could not be felt, and there was no shifting dullness in the flanks. Both testicles were in the scrotum. There was a slight rise of temperature, but this rapidly fell to normal. The pulse was 128.

On rectal examination the pelvis was found to be filled by a large hard mass lying behind and somewhat to the left side of the rectum. The bowel was so tightly compressed that it was impossible to pass the finger beyond the mass. During the examination a burst of flatus suddenly escaped and the distension of the abdomen became distinctly less marked. The urine contained no acetone or diacetic acid.

A status tube was passed at intervals followed by an injection of pituitary extract. The size of the abdomen was much reduced by this procedure but the effect was transient. Occasional enemata produced fair results, but with only temporary effect on the abdominal distension. A radiogram of the pelvis showed nothing abnormal.

Operation

On February 16th the abdomen was opened by a left paramedian incision displacing the rectus outwards. A very small quantity of blood-tinged fluid was noticed in the peritoneal cavity. The large intestine was enormously distended and hypertrophied, being about the size of the inner tube of a bicycle. The lower part of the small intestine also was both distended and hypertrophied. This was less marked higher up and the jejunum appeared quite normal. The pelvis was completely filled by a hard retroperitoneal mass the upper convex surface of which was covered with distended veins and rose well above the brim of the pelvis.

The growth was obviously inoperable. A small gridiron incision was accordingly made near the right anterior superior iliac spine and the mass exposed retroperitoneally incised and some fragments secured for microscopic examination. The general condition of the child not being very good a descending colostomy was performed through the laparotomy incision and a Paul's tube inserted.

Pathological Report

The section shows a remarkable new growth, consisting of a mass of tissue which on close inspection, is seen to be made up of small papillary outgrowths of fibrous stroma covered with epithelium of an elementary type. It is practically certain that this is part of a teratoma. What the tissue is it is impossible to say—it is too slightly differentiated to have a special function or name; this may be the main element of its malignancy, which is evidently of a high order. If the entire aberrant mass could be examined there is little doubt that other tissues would be discovered though in the case of a malignant overgrowth of teratomatous tissue it is quite usual for one type of tissue to become considerably more increased than the remainder.

After-History

The child was fairly comfortable after the operation and the abdomen greatly diminished in size. The chief difficulty was in passing urine and it is probable that the immediate cause of death on March 5th was uraemia. For the last few days the patient was semi-conscious.

Post mortem Examination

The bladder was much distended and its walls very thin. The colon both above and below the colostomy opening had contracted down in a very striking manner. The liver and other viscera appeared normal. A spherical mass of friable tissue the size of a small orange was lying between the rectum and the sacrum—somewhat enveloping the former. This mass, on close inspection appeared to be composed of several different tissues, and contained numerous tiny hard nodules (cartilage). No hairs or teeth were found.

The section shows various tissues including muscular, nervous and epithelial cells, all in a primitive state of development. There can be no doubt that the tumour is a teratoma. There is cartilage and a calcified area in the section but no actual bone formation. The period of partial isolation from the main mass of the foetus must have been quite early.

It would appear to be a matter of doubt whether this tumour was highly malignant or benign. Some of the sections suggest the former but several cases have been described in which similar tumours have eluded discovery until fairly late in life.

I am indebted to Dr. T. A. Knott of the Clinical Research Association for the pathological reports.

DISCUSSION ON
OVERLOOKED CASES OF FOREIGN BODY IN
THE AIR AND FOOD PASSAGES

OPENING PAPERS

I—CHEVALIER JACKSON, M.D., Sc D., F.A.C.S.,
Philadelphia

NOTES ON SYMPTOMATOLOGY AND DIAGNOSIS

It seems necessary at the outset to state that this presentation is from the author's individual viewpoint, which means that of one who metaphorically as well as actually, sees narrowly through a small tube. For a presentation from the broad viewpoint of the internist the reader is referred to the Lunnern Lectures (1924) by Professor Thomas McCrae, who has seen, probably, more cases of foreign bodies in the lower air passages than any other internist. However, all of the present article is clinical in character, and is prepared from carefully recorded data concerning cases seen by the author's associates—Dis Ellen J Patterson, Gabriel Tucker, and Louis H Cleif—and himself.

Of the 1,485 cases of foreign bodies that have come to the Bronchoscopic Clinic during twenty years there have been over 200 that had been overlooked for periods of from one month to thirty six years. A broad consideration of the histories of these cases shows the outstanding fact that the failure to recognize the presence of a foreign body was due, not so frequently to inability to make the diagnosis, as to failure to attach sufficient importance to the consideration of foreign body as a diagnostic possibility. Foreign bodies have been regarded as curiosities of medicine rather than as routine possibilities for exclusion.

A careful analysis of all the cases in which records were adequate, however, shows that the chief factors in the overlooking of the foreign bodies (not in the etiology of the accident itself) in the respective cases are:

- 1 Failure to consider the possibility of foreign body
- 2 Absence of a history of foreign body
- 3 Skepticism as to the possibility of the presence of a foreign body, in some instances even in the face of a very positive circumstantial history of the accident
- 4 Apathetic attitude of the practitioner
- 5 The symptomless interval
- 6 Multiplicity of foreign bodies
- 7 Waiting for spontaneous expulsion of the foreign body
- 8 Simulation, in cases of foreign body of the signs and symptoms of relatively common diseases such as asthma, bronchitis, pneumonia, bronchopneumonia, emphysema, abscess, bronchiectasis and tuberculosis. Encountering daily these common conditions the practitioner does not feel called upon to go out of his way into the realm of seemingly remote possibilities like foreign body. Until the practitioner deems it necessary to exclude foreign body in every case of acute or chronic pulmonary disease foreign body in the lung will continue to be overlooked.
- 9 Lack of emphasis in medical teaching on the exclusion of foreign body in every case of acute or chronic disease of the chest.
- 10 Groundless assumption of passage by bowel
- 11 Character of the foreign body

Absence of a history was frequently a factor. It arose from such circumstances as these:

- 1 The patient being too young to tell of the accident which occurred when older observers were absent
- 2 The patient being unconscious from sleep, epilepsy, coma and the like or oblivious from delirium, shock, emotional excitement, distraction or alcoholic intoxication
- 3 Failure of those present to realize the true character of the initial symptoms
- 4 Forgetting of the accident by the patient or his relatives

5 Fear of ridicule. Not infrequently the attitude of the practitioner first seeing the case has been such that the patient feared he would be considered hysterical or morbidly introspective or even ridiculous, if he mentioned the matter consequently he has omitted mention of the foreign body accident to later physicians.

6 Failure of the practitioner to inquire carefully and persistently for the initial symptoms especially choking and gagging. Many times have we had cases in which the parents at first answered negatively yet on close and persistent questioning were able to recall a choking and gagging attack.

That absence of a history of foreign body accident is of little or no importance diagnostically is proved by over a hundred cases at the Bronchoscopic Clinic. It is very common for babies to be brought in with maize, milk-leaves, water-melon seeds, safety-pins, and all sorts of foreign bodies, with no knowledge on the part of parents as to how the accident happened. Many cases have occurred also in adults. For instance, an intelligent retired business man, sober and wide awake, while spurring his own throat aspirated the cap off an atomizer, nearly as large as a thumb, without knowing it. It was discovered in the right bronchus by means of the x-rays while the patient was under climatic treatment for supposed tuberculosis, and was removed bronchoscopically. Obviously, if an intelligent man, wide awake and sober, can aspirate so large a foreign body without knowing it, a negative history may be worthless diagnostically.

Ignoring a History of a Foreign Body

It is remarkable to note how frequently a clear and circumstantial history of a foreign body accident has been brushed aside. This has happened even in the face of the most positive and clear-cut signs and symptoms, and in many instances we have been amazed at the positiveness with which the practitioner has told the patient that the symptoms and signs could not be due to a foreign body, and that no foreign body was present. We are often not quite sure there is no foreign body present, and often keep a patient under observation a long time before deciding in the negative. It frequently happens that we do diagnostic bronchoscopy before reaching a decision. Occasionally, when this procedure is negative, we are still uncertain as to the possibility of a small fragment of non-opaque foreign body in a minute bronchial branch, which of course cannot be entered. Such cases require watching, sooner or later signs will develop. There is only one way, it seems to us, of avoiding this error in every case in which there is the slightest intimation of a foreign body accident or of the patient having had an attack of choking, gagging, strangling, or coughing, should be regarded as *prima facie* a case of foreign body. Unlike our good old English common law in which the accused is not to be regarded as innocent until proven guilty, a foreign body should be regarded as being present until its absence is proven by every means at our command. Our justification for this rather strong statement is the fact that our histories show dozens of cases in which a child, after having choked and gagged with food or some foreign substance in his mouth, was taken to a practitioner or to a dispensary, or to an out-patient clinic, when entirely symptomless. The temperature, pulse, and respirations being normal, and a cursory physical examination being negative, the parents were reassured and sent away. In some instances they were told to return if the child seemed unwell. In either class of case the symptomless interval, often prolonged, prevented connection of the initial symptoms of foreign body aspiration with the slow and tardy development of symptoms. Patients with any history, however vague, of choking, gagging, or strangling, or of any circumstance suggestive of foreign body should be put through all the diagnostic steps enumerated below, and should be kept under close daily observation until it is clearly evident that no foreign body is present.

Apathetic Attitude of some Physicians

In mailed contrast to the practitioner who thinks there could be no foreign body in the lung because the patient is not very ill, there have been a few instances of a "let alone" attitude, or at least a failure to realize the ease and relative certainty with which a foreign body can be bronchoscopically removed from the lung.

Symptomless Interval
Of all the factors in the overlooking of foreign bodies in the lungs the outstanding one is the symptomless interval. In aspirated metallic foreign body, if non-obstructive, may remain for months in the tracheo-bronchial tree without a single symptom. During this time the accident has been forgotten by the patient, or, if it has not, this symptomless interval is used deductively for the occlusion of foreign body as an utter impossibility. All of us have had a crumb of bread or a drop of water, or a drop of sugar-laden saliva, get into our larynx, and we remember the violent strangling cough provoked, and the subsequent lingering irritation. With this experience in mind it naturally seems incredible that a sharp pin or a sharp and rough tack could remain in the tracheo-bronchial tree for months without a single abnormal sensation or a single symptom. This is one of the chief factors in the overlooking of foreign bodies in the lungs. If the patient comes in at a later stage, when suppuration has been established, the practitioner may, if he considers the possibility of a foreign body, ask the patient if he had swallowed or inhaled any foreign substance at the time the cough began. The foreign body accident may have occurred months before the cough and expectoration were so obtusive as to be noticed by the patient.

It is therefore necessary to inquire closely and persistently as to any recollection of an attack of choking, gagging, or struggling at any time, no matter how remote. The symptomless interval in cases of oesophageal foreign body is not so marked as in the bronchial cases. In one of our patients an intelligent woman aged 43 the subjective sensation of foreign body had so completely disappeared that I was inclined to let her go home. Yet Dr. Gabriel Tucker insisted on oesophagoscopy examination because of a slight irritation of the opaque capsule. He removed a spicule of bone that had penetrated the mucosa and would have almost certainly caused mediastinal trouble. In a number of other cases we got a history of the patient having thought himself rid of the foreign body because of the disappearance of subjective sensations. In most cases adults have felt a sensation at least during deglutition, but most of the cases of overlooked foreign body in the oesophagus have occurred in children too young to tell of their sensations.

Multiple Foreign Bodies

Since the warning in the early days of the work we have been constantly on our guard against overlooking other foreign bodies after the removal of the first one or more. In the case of foreign bodies opaque to x-rays this is easily guarded against by the rigidly enforced rule to have an "after x-ray," as we call it, in every case. Incidentally this guards against chargin in case of later aspiration or swallowing of another foreign body by a child or a hysterical or a demented patient, as has occurred a number of times but the chief purpose is to guard against overlooking in case of unsuspected multiple foreign bodies. In one case there were in all, thirty-seven foreign bodies. In the case opaque to x-rays, others not. Following on many of them opaque to x-rays, patient radiologically examined some of the bronchus removed in entangled "burr" of the bronchus to the tuberosities of the ischia, we were prepared after having removed an entangled "burr" of the multiple intestinal foreign bodies. This undoubtedly saved the child's life, because one of the foreign bodies, a needle, remained ten days in one place. This we regard as a lesson learned because we have found that sharp foreign bodies do not as a rule, penetrate the intestinal wall, but ulcerate through it. Therefore we call upon the abdominal surgeon to consider the advisability of operation after a sharp foreign body has been in one spot as long as four days. In this case we waited a little longer than we should otherwise have done, because of the serious state of the child from ulcerative oesophagitis and tobacco poisoning. The abdomen was opened by Dr. Thomas A. Shallow who found that the needle had ulcerated its way through the intestinal wall for a distance of half the length of the needle. Its slow progress through had allowed time for protective adhesions to wall off the infection so that general peritonitis had not followed, and the child made a perfect recovery.

Multiple Dental Foreign Bodies
A man aged 40 thirteen months prior to admission had a tooth extracted under gas anaesthesia the tooth breaking into a number of fragments. Two weeks later cough and fever developed for which a physician treated the patient under a diagnosis of acute bronchitis. Blood tinged sputum appeared and the patient consulted another physician who ordered an x-ray examination. This revealed an amalgam filling which was removed through the mouth by a bronchoscopist. Cough and foul expectoration persisting the patient was treated for six months by autogenous vaccines for pulmonary abscess with improvement. The cough and expectoration persisting though less another x-ray examination was made which revealed a fragment of tooth in the right bronchus. For the removal of this he was sent to the Bronchoscopic Clinic for recovery.

Comment—This case strongly emphasizes the importance of our rule always to have a thorough careful ray study made after bronchoscopic removal of a foreign body. It illustrates also the necessity for remembering that foreign bodies especially dental foreign bodies may be multiple. It also confirms our oft-repeated advice to exodontists to match together all fragments of teeth and filings to see if all are accounted for. As the course of the abdominal surgeon counts the sponges if anything is missing a radiological examination should be made at once. Another point is that cough or any bronchial symptom after (even months after) extraction of a tooth should be considered a case of foreign body until proved otherwise. Such a rule might have prevented a year of lung suppuration in this case.

Waiting for Spontaneous Expulsion

This was the cause of prolonged sojourn (one month to twenty years) of foreign bodies in the lung in a number of cases. A symptomless interval following, and the patient drifting into the care of another physician, the foreign body was overlooked in a number of such cases that finally came to the Bronchoscopic Clinic for removal of the intruder. It is impossible to compile general statistics that will afford useful percentages as to the frequency of spontaneous expulsion, but of the cases that have come under our observation only about 3 per cent of the foreign bodies known to have reached the bronchi have been coughed up. In some of these cases the coughing up could not be said to have been entirely spontaneous, since they occurred after a preliminary bronchoscopy for the dilatation of a bronchus narrowed by secondary inflammatory processes, or chronic. We shall probably do full justice to our patients if we tell them that while there is a possibility of the foreign body being coughed up, it rarely happens, and waiting is dangerous.

Erroneous Diagnoses

In 218 cases of overlooked foreign bodies in the air and food passages the following erroneous diagnoses were known to have been made: pneumonia, bronchopneumonia, empyema, tuberculosis, asthma, bronchiectasis, pulmonary abscess, enteric fever, malaria, gastritis, cyclic vomiting. In addition to the foregoing there were correct diagnoses of lesions present, but the foreign body as the primary factor was overlooked. These cases included not only bronchiectasis, pulmonary abscess, empyema, and pneumothorax, but secondary forms, such as myocarditis.

Pneumonia

It is amazing to look over our records and find how frequently pneumonia was the erroneous diagnosis, not only in the cases in which the foreign body was overlooked, but in cases in which the foreign body was known to be present. We are often asked if it is safe to remove a foreign body during the "pneumonia." As my colleague Professor McCrue will tell you, pneumonia, as the term is understood by internists, is exceedingly rare as a complication of foreign body in the lung and why misinterpretation of the physical signs leads to this erroneous diagnosis. We often see the signs of a supposed pneumonia promptly disappear after the removal of an obstructive foreign body in the lung. I am not qualified to speak on any matter dependent upon diagnosis by physical signs but I fortunately have had close co-operation with Professor McCrue and other leading internists, who assure me that these patients do not have true lobar pneumonia. A very large proportion of patients with overlooked foreign bodies give a history of recurrent attacks of supposed pneumonia, which are evidently conditions due to inter-

mittent obstructions to drainage, the physical signs of which are misinterpreted. Dr. Willis F. Manges, who has seen more of these cases than any other roentgenologist, has demonstrated over and over again that the x-ray signs of pneumonia are absent in these cases.

Empyema

It has been pointed out by Professor McCrae in his writings, and very frequently on our patients clinically, that while the misinterpretation of the physical signs in cases of foreign body as indicating pneumonia is open to just criticism, it is not surprising that the erroneous diagnosis of empyema has been made by misinterpretation of the signs elicited in drowned lung and atelectasis due to foreign body. The differentiation by physical signs will be considered by Professor McCrae. Of course, pleural involvement and even rupture of the suppurating focus into the pleura may occur in cases of foreign body with obstructed upward drainage, but it is rare, an erroneous diagnosis of empyema where none exists is quite common. Over a hundred of our cases had been needed with negative results before coming to the clinic, and in twenty-seven rib resection had been done to explore a pleura that was found normal. In other cases the operation was arranged for and indications ordered for operative localization, but, these showing a foreign body, the operation was abandoned and the child was referred to the clinic, where removal of the foreign body caused disappearance of the signs erroneously interpreted as those of empyema. The following cases will serve as examples of the relatively frequent error of overlooking a foreign body under an erroneous diagnosis of empyema.

A boy aged 6 choked and coughed while playing with a tack in his mouth. The boy and his mother were both sure that the tack went down, but when the child became ill two days later the physician called disbelieved this and made the diagnosis of grippe. A week later the diagnosis was pneumonia. A few weeks later another physician made a diagnosis of abscess following lobar pneumonia. A surgeon called in made a diagnosis of empyema, needing was negative but two ribs were resected. The pleura being found normal, the wound was closed and primary union was obtained. Then, after four months a radiogram was taken and the mother's constant contention that a tack was the cause of the child's illness was verified.

This case illustrates the attitude of some men toward the possibility of foreign body as a cause of pulmonary disorder and indicates the importance of excluding drowned lung from foreign body obstruction in every case of supposed empyema. We have had a large number of similar cases.

A girl, aged 3, had been ill for a year and nine months. She had been treated for bronchitis and pneumonia. A diagnosis of left-sided empyema was made and external drainage was advised. Preparatory localization with the x-rays was ordered. This revealed a screw in the left lung with a large area of 'drowned lung' but no evidence of empyema. The child was then referred to us. She was extremely ill with septic fever from the pulmonary suppuration but ultimately made a good recovery after the bronchoscopic removal of the screw. Close questioning of the mother elicited the fact that twenty months before, when the child was 16 months of age, it had an alarming attack of choking, coughing and gagging while sitting on the floor. It was some time after this that bronchial symptoms began, and the mother had not connected the incident with the lung condition nor had she mentioned it to the medical men who were about to do a thoracotomy for a supposed empyema, but the outstanding fact remains that she was never questioned closely as to a paroxysm of choking, gagging, and coughing. Our records show that these initial symptoms are rarely absent though they may not have been observed or remembered. Close questioning will sometimes elicit recollection. Regardless of history of foreign body, as Professor McCrae will explain, drowned lung should be distinguished from empyema.

Pleurisy

Pleurisy was the erroneous diagnosis in at least seven cases, in which there probably was no pleural involvement. In some of the cases the practitioner probably had in mind effusion because of the impaired percussion note at the base due to atelectasis or drowned lung.

'Cold on the Chest'

This was most often a diagnosis by the laity, but it was an important factor in the overlooking of foreign bodies by physicians. It most often occurred in cases of seeds, nut-kernels, nut-hells, bones, and other substances in foods. The usual way in which children get fragments of nut-kernels into the lungs is in eating nut-candies and nut-

cakes. Choking while eating such things is usually considered of little moment by parents, and thus leads to the primary overlooking. The laity are obsessed with the idea that any little 'draught' can cause a 'cold,' and every child is exposed to a draught every day of its life. The parents, when finally they take the child to a physician, tell with much circumstantial detail of baby having 'caught a cold' which did not 'clear up.' This primary diagnosis by the laity has unconsciously led many practitioners away from all thought of a foreign body. Close questioning as to choking while eating in every case of the layman's 'cold on the chest' in the case of babies, and thoroughly following up the suggested means of exclusion of foreign body, will, by early diagnosis, enable the bronchoscopist to save the lives of many children.

Asthma

Asthma was the erroneous diagnosis at some stage of the case in so many (48) of our cases that we feel it is not unreasonable to urge that foreign body should be excluded in every case before finally confirming a tentative diagnosis of asthma. In some of our cases the only asthmatic symptom was the presence of the 'asthmatic wheeze,' which is diagnostically so valuable a symptom of any kind of foreign body in the larynx, trachea, and larger bronchi, but in other cases the simulation of the prominent features of bronchial asthma was so close that little criticism could attach to the practitioner who made the erroneous diagnosis. For instance, it is quite common in cases of vegetable foreign bodies to get a definite statement that the child has been awakened suddenly in the night with a violent paroxysm of coughing, accompanied by loud wheezing, possibly also strangling and cyanosis. These attacks in cases of vegetable foreign bodies are probably due to the accumulation of secretions during the first sleep of the tired child, secretions being usually abundant in cases of foreign bodies of this type. Asthmatic symptoms were sufficiently prominent to mislead the practitioner in 18 cases of foreign body, not in the passages, but in the oesophagus. There were three classes of these cases. In some cases there was wheezing due to compressive narrowing of the tracheal lumen by the presence of a relatively large foreign body on the membranes and, in children, very yielding 'putty wall' between the oesophagus and the trachea. In other cases there was overflow of secretions and food into the larynx. In a third group of cases trauma by the parent's finger in efforts to remove the foreign body or trauma from the use of instruments by our predecessors in the case had caused acute oedematous laryngitis.

Diphtheria

A croupy cough is a logical sequence of foreign body in the larynx, yet tolerance to the presence of a foreign body in the larynx is so quickly established that its presence may not be suspected. A symptomless interval of a few hours, or in some cases even a few weeks, before croupiness started, was noted in most of our cases of laryngeal foreign bodies. During the interval there was little or no noticeable cough in cases in which the foreign body was fixed. The unsuspected presence of a safety pin in the larynx in three of our patients led to the administration of antitoxin. One of these patients, aged 2 years, was sent in for a supposed post-diphtheritic stenosis of eight months' duration. Tracheotomy had been performed at the time of the supposed diphtheria, when the child was 14 months of age. Removal of the open safety pin resulted in cure and decannulation without any treatment for stenosis. In the other two safety-pin cases tracheotomy had not become necessary, one of the patients was sent in because the croupiness did not disappear within a few weeks after the administration of antitoxin, the other patient, after three months, developed swelling in the front of the neck, for which an x-ray examination was made. Similar cases have been reported by Henry B. Oton and others. Diphtheria has been much more frequently the erroneous diagnosis in cases of foreign body, not in the larynx, but in the trachea and bronchi. This is particularly true of vegetable foreign bodies, because of the intensity of the local reaction to their presence.

especially in children. Logan Turner pointed out many years ago the peculiar histological structure of the subglottic larynx in children, which renders them peculiarly subject to oedematous subglottic laryngitis. Crampness in diphtherial children is due chiefly to this same state of subglottic oedematous laryngitis, though in diphtheria the subglottic region is reached by extension from above, while in tracheo bronchitis due to vegetable foreign body the extension is from below. Vegetable foreign bodies led to an erroneous diagnosis of diphtheria in 17 cases. In 4 of these diphtheroid bacilli were present, but as no characteristic membrane was found the presumption was that these patients were croupous. The foreign bodies included peanut kernels, walnut kernels, beech-nut shells, maize, and water melon seeds.

Winter Bronchitis

This was a symptom, and had been the diagnosis, in 18 cases of overlooked foreign bodies, and it is interesting to note that in 5 of the 18 cases the foreign body was in the oesophagus, not in the air passages. Tracheo bronchial symptoms are present in almost all cases of obstructive foreign bodies in the oesophagus. Referring, however, only to "winter bronchitis" in cases of prolonged oesophageal sojourn of an overlooked foreign body, there were 2 cases in which the foreign body had ulcerated through the "puity wall" into the trachea. In 3 other cases there was only the aspiration of the overflow to account for the bronchial symptoms prominent only during the winter.

In the other 13 cases in which the diagnosis of "winter bronchitis" had been made, there had been an overlooked foreign body in the tracheo bronchial tree. One very instructive case of this kind is the following.

Serew in Bronchus for Twenty Months

A female child aged 3 months developed in February a loose cough without much systemic disturbance. Details as to the physical signs found are not available but they were thought to have disappeared along with all the symptoms except slight wheezing during the following summer. In the autumn the cough returned became loose and productive and continued throughout the winter seeming to excuse a diagnosis of winter bronchitis. The second summer the symptoms moderated but did not disappear. In November (twenty months after the initial symptoms) a diagnosis of pneumonia followed by abscess and empyema was made, and external operation for drainage was deemed necessary. For localization for operative purposes an x-ray examination was made, and the shadow of a metallic foreign body, a serew, was found. The mother then made the statement that she remembered that the child (then 3 months of age) had choked and gagged while sitting on the floor a few weeks prior to the onset of the bronchial symptoms. The child was then sent to the Bronchoscopic Clinic where the serew was removed by bronchoscopy through the mouth. There was no pneumonia, no empyema, and the child made a perfect recovery under open air conditions, without any external procedure.

The clearing up of the symptoms of purulent bronchitis during the first summer after the aspiration of the serew, notwithstanding the continued presence of the serew, is of utmost importance. That the serew was present during this period is proved by occasional asthmatic wheeze. In explanation of the summer abatement of the symptoms it seems a logical inference that there would be greater resistance to the secondary suppurative processes (which, of course, constituted the basis of the incomplete diagnosis of "winter bronchitis") during the open-air environment of summer. Supporting this inference we have the observation elsewhere mentioned of the great general improvement and the gain of 15 lb under an outdoor antituberculosis regime, notwithstanding the presence of an overlooked beef bone in the bronchus.

It would seem wise carefully to exclude foreign body in every case of "winter bronchitis," and especially to be on guard against the inference that disappearance of symptoms in summer time excludes the possibility of foreign body. Other important points are the mistaken diagnoses of pneumonia and empyema, which were not present. The pathology on which these erroneous diagnoses were made was "drowned lung" a condition in which all the passages are filled with pus without breaking down of the structural elements. Another case illustrative of overlooked foreign body erroneously diagnosed "winter bronchitis" is the following.

Brass Tag fastener in the Bronchus for Seven Years

A woman aged 23 had cough, foul expectoration, and slight fever at times during seven years. During the last two years there had been some loss of weight but the patient was not emaciated nor did she have a septic look. The exacerbation of the symptoms in winter with almost complete disappearance in summer had led to a diagnosis of winter bronchitis. During the last winter the dullness at the base had led to a diagnosis of empyema, but needling proved negative. An x-ray examination made by Dr. Willis F. Manges showed no fluid in the pleura, but revealed a metallic object in the lower lobe of the right lung with an abcess below it. The mother and the patient recalled the choking of the patient then a girl of 16 by a tag fastener while at work in a stocking factory. The accident had been mentioned to the earlier physicians in the case but the possibility of foreign body was brushed aside so brusquely by them that the mother did not mention the matter to later physicians. Bronchoscopic removal resulted in a perfect cure without any external drainage; all the symptoms disappeared in six months. Eleven years later an x-ray examination by Dr. Manges revealed no abnormality in the lungs and physical examination by Dr. S. Solis Cohen showed no abnormal signs. The patient now fourteen years after bronchoscopic removal weighs 172 lb and is in perfect health. She has married and has a robust 8-year-old son.

The severe exacerbation of symptoms during the winter months and their almost complete subsidence during the summer is very striking and was noted by the family and by a number of physicians. At the bronchoscopy it was noted that obstruction of the bronchus was not complete. Our experience in many similar cases indicated that foreign body should be excluded in every case of what is rather loosely termed "winter bronchitis," and especially so in young subjects. The amelioration of the symptoms in summer has been almost exclusively in the cases of foreign bodies not of vegetable character, and not completely obstructive. In case of complete obstruction to drainage the symptoms usually persist and increase progressively in severity. Vegetable foreign bodies in the bronchus of children, even if not completely obstructive at first, soon become so, and, if unremoved, prove fatal too soon for the seasonal differences to be observed.

Tuberculosis

Many patients are sent in for removal of foreign bodies after months or years of treatment for supposed tuberculosis in institutions. Such cases are becoming somewhat less common since the intensive work in all phases of diagnosis and treatment of pulmonary tuberculosis has led to more critical work in "non-bronchial" cases, and routine x-ray examination in all cases. There is no reason why a tuberculous patient should not aspirate a foreign body as well as a normal person, yet among the hundreds of cases of foreign body in the lung that have come to the clinic we have found tubercle bacilli present in only one, and that a mere coincidence. This absence of genuine tuberculosis is interesting in connexion with the fact that all the older textbooks stated that foreign body in the lung ended in phthisis pulmonalis. This was, of course, prior to the discovery of the bacillary nature of tuberculosis, when chronic pulmonary septic conditions were not accurately differentiated.

Malaria

The intermittent temperature which in some of our cases has been singularly regular in its fluctuations has in a number of instances led to an erroneous diagnosis of malaria. One is reminded of the wholesale mistaken diagnosis of malaria in what was really typhoid fever demonstrated by Professor Osler in Brooklyn many years ago. Such a mistake could only be made through lack of care and thoroughness in making a diagnosis. The differential diagnosis between malaria and chronic pulmonary sepsis is easy. The important thing is always to exclude foreign body in cases of chronic pulmonary sepsis.

Enlarged thymus gland was the erroneous diagnosis in many cases in some the radiologist being unfamiliar with the x-ray diagnosis of non-opaque foreign body, had overlooked it and had treated the child with the therapeutic ray. In other cases the diagnostic examination for suspected thymic hypertrophy had revealed the presence of metallic foreign body. The following case is illustrative of a number of phases of this subject.

admission, and some of these were fatal. In two cases the foreign body had been driven into the mediastinum. One of these patients recovered after peroral bronchoscopy and removal of the foreign body from the mediastinum.

After-Care

Prolonged suppuration due to a foreign body lodged in a bronchus is kept up chiefly by the presence of the intruder itself. After removal usually no treatment other than rest and fresh air is necessary. Only in one case have we found it necessary to dilate a fibrous stricture after removal of a foreign body. This we did bronchoscopically. In many cases bronchoscopic dilatation was necessary before removal to get at the foreign body, but further dilatation during convalescence was necessary only the once.

After-Results in Overlooked Cases

One of the most remarkable things is the recuperative power of the lung from the seemingly very serious pathological condition produced by a foreign body after the intruder has been removed. In cases of non obstructive metallic foreign bodies, recovery is a logical sequence. On the other hand, bronchial obstruction with years of extensive imperfectly drained suppuration due to the continued obstructive presence of a foreign body is usually followed by complete recovery, and this in a time relatively so short as to be in marked contrast to the progress of suppurative pulmonary disease of other etiology. It would be out of place here to cite many cases, and it is unnecessary since many have been published. A boy with a metallic umbilical tip in his lung from 2 to 9 years of age, with very extensive pathological changes in his lung, is now, six years after removal, perfectly well. He has no cough, and no expectoration, the physical signs and the x rays, we are assured by his father, a physician, give no evidence of any abnormality in the lung. A woman with pulmonary abscess and almost moribund from twenty-six years' sojourn of a glass collar button in the lung, is entirely free from cough and expectoration and weighs 186 lb. Another woman is practically well after the removal of a safety-pin that had been in her lung for thirty-six years. Many other cases could be cited to show that prolonged suppuration from foreign body is not often followed by permanent changes of the bronchiectatic type, which are so common after other conditions, such as pneumonia, influenza, and pertussis.

CONCLUSIONS

Of the 1,485 cases of foreign body in the air and food passages that have come to the Bronchoscopy Clinic, over 200 had been overlooked for periods of from one month to thirty six years. An analysis of these cases as to the causes leading to the failure to make the proper diagnosis leads us to the following conclusions:

1 Prolonged sojourn of foreign bodies in the air and food passages is not due so often to inability to make a diagnosis as to the fact that foreign body does not occur to the practitioner as a diagnostic possibility. As Sir James Mackenzie has said, it is the general practitioner who sees the beginnings of disease. That he does not include foreign body as a diagnostic possibility in every case of acute or chronic disease of the subpharyngeal airway is the fault of medical education, which rarely includes foreign body in the list of diagnostic possibilities to be excluded in every case of pulmonary disease.

2 Simulation of the signs and symptoms of relatively common diseases such as asthma, bronchitis, pneumonia, bronchiopneumonia, empyema, abscess, bronchiectasis, and tuberculosis. Encountering daily these common conditions, the practitioner does not feel called upon to go out of his way into the realm of seemingly remote possibilities such as foreign body. Until the practitioner deems it necessary to exclude foreign body in every case of acute or chronic pulmonary disease foreign body in the lung will continue to be overlooked.

3 A common reason why foreign bodies in the air and food passages are overlooked is the failure to attach sufficient importance to the initial symptoms of choking and gagging with any substance even food, in the mouth. These symptoms are almost never absent. In a child no one may have

been present to observe them, but more often they have been forgotten, and if so, only close cross questioning will bring them to mind.

4 The chief etiological factor in the overlooking of foreign bodies in the tracheo bronchial tree is the symptomless interval between the initial symptoms of choking and gagging and the later onset of pulmonary symptoms. This interval may last for a period varying from a few hours to two years, and is rarely absent. During the symptomless interval all symptoms, including cough, are slight or entirely absent. If the practitioner should think of foreign body at all he is apt to ask if the patient got anything "down the wrong way" at the time the cough began.

5 Our experience leads us to believe that if every practitioner who has children to treat would be as careful to exclude foreign body in the air passages as he is to exclude Banti's disease, many lives would be saved.

SYMPTOMATOLOGY AND DIAGNOSIS OF FOREIGN BODY IN THE AIR AND FOOD PASSAGES (Summary)

Since the prevention of the overlooking of foreign bodies in the air and food passages necessitates full appreciation of the essential points of symptomatology and diagnosis, it seems well to append here the summary of the points formulated by the author from the cases observed during the last thirty years.

Initial symptoms are choking, gagging, coughing, and wheezing, often followed by a symptomless interval. Foreign body may be in the larynx, trachea, bronchi, nasal chambers, nasopharynx, fauces, tonsil, pharynx, hypopharynx, oesophagus, stomach, or intestinal canal, or may have passed by bowel, been coughed out or expectorated, with or without the knowledge of the patient. Initial choking, etc., may have escaped notice, or may have been forgotten.

Laryngeal Foreign Body

One or more of the following laryngeal symptoms may be present: Hoarseness, croupy cough, aphonia, odynophagia, haemoptysis, wheezing, dyspnoea, cyanosis, rhinœa, or subjective sensation of foreign body. Croupiness usually means subglottic swelling. Obstructive foreign body may be quickly fatal by laryngeal impaction on respiration or on abortive coughing expulsion. Lodgement of a non obstructive foreign body may be followed by a symptomless interval. Direct laryngoscopy for diagnosis is indicated in every child having laryngeal diphtheria without faucal membrane (No anaesthetic, general or local).

In the presence of laryngeal symptoms, think of the following:

- 1 Foreign body in the larynx
- 2 A foreign body loose or fixed in the trachea
- 3 Digital efforts at removal
- 4 Instrumentation
- 5 Overflow of food into the larynx from oesophageal obstruction due to foreign body
- 6 Oesophago-tracheal fistula from ulceration set up by a foreign body in the oesophagus followed by leakage of food into the air passages
- 7 Laryngeal symptoms may persist from the trauma of a foreign body that has passed on into the deeper air or food passages or that has been coughed or expectorated
- 8 Laryngeal symptoms (hoarseness, croupiness, etc.) may be due to digital or instrumental efforts at removal of a foreign body that never was present
- 9 Laryngeal symptoms may be due to acute or chronic laryngeal diphtheria, pertussis, infective laryngotracheitis, and many other diseases
- 10 Deductive decisions are dangerous
- 11 If the x-ray examination is negative laryngoscopy (direct in children indirect in adults) without anaesthesia general or local is the only way to make a laryngeal diagnosis
- 12 Before doing a diagnostic laryngoscopy preparations should be made for taking a swab specimen and for broncho-copy and oesophagoscopy

Tracheal Foreign Body

(1) Audible slap (2) palpatory thud and (3) asthmatic wheeze are pathognomonic. The tracheal flutter has been observed by McCrae. Hoarseness, dyspnoea and cyanosis are often present. Diagnosis is by radiology, auscultation, palpation, and

bronchoscopy Listen long for an "audible snap," best heard at open mouth during cough The asthmoid wheeze is heard with the ear or stethoscope bell (McCrac) at the patient's open mouth History of initial choking gagging and sneezing is important if elicited, but is valueless negatively

Bronchial Foreign Body

Initial symptoms are coughing choking asthmoid wheeze etc noted above There may be a history of these or tooth extraction At once or after a symptomless interval cough blood streaked sputum metallic taste or special odour of foreign body may be noted Non-obstructive metallic foreign bodies afford few symptoms and few signs for weeks or months Obstructive foreign bodies cause few signs for weeks or months, they give rise to atelectasis, drowned lung and eventually pulmonary abscess Lobar pneumonia is an exceedingly rare sequel Vegetable organic foreign bodies—pearl kernels beans watermelon seeds etc—cause at once violent laryngitis with toxaemia cough fever etc the being inversely to the age of the child bodies after months or years produce embargues which cause chills fever sweats emaciation, clubbed fingers incurved nails cough foul expectoration haemoptysis in fact all the symptoms of chronic pulmonary sepsis abscess bronchiectasis etc also signs which may suggest pulmonary tuberculosis but the apices are normal and tubercle bacilli are absent from the sputum

Physical Signs

Mere mention of physical signs is included here for the sake of completeness Those interested in this subject should not fail to read the articles by Professor Thomas McCrac, who has seen more cases of foreign body in the air passages than any other internist His experience is analysed and presented in form for the utmost usefulness to the clinician in the *Lundgren Lectures for 1924*

Radiology is a most valuable diagnostic means, but careful study of the physical signs by an expert is absolutely essential in all cases Expert x-ray work will usually show all metallic foreign bodies and many of less density, such as teeth, bones, shells, buttons, etc If the x-ray examination is negative for foreign body, but indicates bronchial obstruction, diagnostic bronchoscopy should be done

Pearl kernels and water-melon seeds in bronchi (and, rarely other foreign bodies) produce obstructive emphysema of the invaded side Radioscopy shows the diaphragm flattened, depressed, and with a less excursion on the invaded side, at the end of expiration the heart and mediastinal wall move over toward the uninvaded side, and the invaded lung becomes less dense than the uninvaded, from trapping of the air by the expiratory valve-like effect of obliteration of the "foreop spaces" that during inspiration afford air ingress between the foreign body and the swollen bronchial wall This partial obstruction causes obstructive emphysema, which must be distinguished from compensatory emphysema, in which the ballooning is in the unobstructed lung, because its fellow is wholly out of function through complete "corking" of the main bronchus of the invaded side (Ighite-Manges) Obstructive atelectasis (Manges) occurs when the obstruction is complete, air below the obstruction is absorbed, the lung collapses, and the mediastinum moves over to satisfy the vacuum Both emphysema and atelectasis call urgently for bronchoscopy, whether there is a history of foreign body or not

Oesophageal Foreign Body—After initial choking and gagging or without these, there may be a subjective sense of a foreign body, constant or, more often on swallowing Painful and difficult deglutition or aphagia may, or may not, be present Haematemesis and fever may occur from the foreign body or from rough instrumentation Symptoms referable to the air passages may be present, due to (1) overflow of secretions on attempts to swallow through the obstructed oesophagus (2) erosion of the foreign body through the oesophagus into the trachea, or (3) trauma inflicted on the larynx during attempts at removal, digital or instrumental, the foreign body still being present or not

Diagnosis is by x-rays first without then if necessary, with a capsule filled with an opaque mixture Flat objects, like coins always lie with their greatest diameter in the coronal plane of the body, when in the oesophagus, in the sagittal plane when in the trachea Lateral, antero-posterior and sometimes also quartering radiograms are necessary One taken laterally, low down on the neck but clear of the shoulder, will often show a boue, invisible in the antero-posterior exposure

II—THOMAS McCRAL, M.D., F.R.C.P., Professor of Medicine the Jefferson Medical College

Let me pay a very pleasant compliment to a worker in internal medicine by asking him to take part in a discussion in your Section This association is necessary if we are to improve our handling of the problem of foreign bodies in the air passages You have the right to ask of the general practitioner and the world in internal medicine that they should be alert and make the diagnosis promptly We have the right to ask that certain of you acquire such skill in bronchoscopy that we can refer patients to you with the assurance that they will be skilfully handled, and that, if necessary, a bronchoscopy for diagnosis can be done with perfect safety May an outsider make a suggestion? It is that in the larger cities one man, or several men working together, be encouraged to devote special attention to bronchoscopy It is only in this way that the highest efficiency can be maintained It may require some generosity of spirit for other men and other hospitals to refer these patients to one man and one hospital in a community, but in this way the best may be done for the patient

Professor Jackson has discussed in detail the causes responsible for a failure to recognize the presence of a foreign body in the air passages Nothing need be added to his summary, and perhaps my part is best filled by discussing some of the problems in physical diagnosis which are involved Emphasis must always be placed on the importance of the failure to consider its possibility To lessen this mistake a steady process of education is essential So long as a foreign body in a bronchus is regarded as something like a fairy tale little progress can be made At our attitude, before my education in this particular was undertaken by Dr Jackson, was to regard it as such a remote possibility that it did not enter into practical work An interesting result of the spread of knowledge regarding foreign bodies is seen in the Jefferson Hospital, to which more and more patients are being sent under the suspicion that they may have aspirated some substance The proportion of suspicious cases in which no foreign body is found is steadily increasing, which is encouraging Those of us who are teachers should impress on our students the importance of this subject

A brief statement of some of the problems connected with the physical signs and diagnosis may be made There is no rule of thumb by which the presence of a foreign body can be recognized, but there are general principles which assist greatly The symptoms and signs must be carefully observed and then thoroughly studied If this is done the majority of the cases are easily recognized, but there is a small group in which the interpretation of the signs is perhaps as difficult as any problem in physical diagnosis The x-ray study, in good hands, is of great value, but very often, unless the physical signs are properly interpreted, this is not considered necessary and consequently is not done Physical signs cannot determine the character of an opaque object as an x-ray study can, but as a general rule physical diagnosis should determine the presence of a foreign body just as accurately In the case of a non-opaque foreign body unless the x-ray worker is expert and can interpret the changes in the lung, the internist has rather the advantage It should always be a matter of team work between the two methods

Certain divisions can conveniently be made—as, for example, between (1) foreign bodies of vegetable nature and (2) other substances, or (1) the general symptoms and signs, and (2) the local signs The possibilities for variation are many A few of these may be discussed If a foreign body gains entrance to a bronchus certain mechanical results follow (a) the bronchus is plugged completely (b) the bronchus is partially obstructed (c) the action may be ball valve letting air in but not permitting it to pass out and (d) there may be variations such as are due to secretions plugging a bronchus entirely for a time and then escaping so that air can pass Lastly, some objects such as a common pin may cause no obstruction and the only physical sign is decreased expansion on the affected side The resulting signs in the affected portions of lung evidently may vary greatly

3 Repeated observation at short intervals if there is any doubt

4 An x-ray study should be made, but not to take the place of physical diagnosis. The internist should endeavour to make out as much as the radiologist

GENERAL DISCUSSION

DR WILLIAM MILLIGAN (Manchester) said that he desired to thank Dr. Chevalier Jackson for what he thought was a "record" communication, not only with regard to its wealth of material, but also with regard to the masterly manner in which it had been presented to the Section. Many of the points raised were of great practical importance. He regarded the intimate co-operation with the radiologist as of the utmost value, but where a negative report was given he thought that in any doubtful case an endoscopic examination should always be made. The foreign body might not be opaque to x-rays, and disastrous results might ensue if the endoscopist did not proceed to make an examination. Then, again, he was in favour of a very complete examination of the whole throat and of a second x-ray examination after removal of the foreign body, as other foreign bodies might be present. He gave illustrations of such cases. The presence of a persistent cough without any very definite explanation called for a thorough search of the respiratory tree, as foreign bodies had a curious way of finding their way into the bronchi without the individual being aware of how they got there. He had known patients diagnosed and treated for tuberculosis for years, but who had recovered entirely after the removal of an unsuspected foreign body. He considered that a very severe cross examination of patients and then history should always be made in doubtful cases, as much useful information was often forthcoming as a result. In diseased conditions of the air passages and of the lungs endoscopy was gaining a very important place, and he thought that greater attention should be given to it in the medical curriculum.

DR IRWIN MOORE (London) associated himself with others in expressing his great pleasure at being present on this memorable occasion to share in the welcome and congratulations offered to Professor Chevalier Jackson. He would like to ascertain from him details as to the methods he employed in dealing with tooth-plates imbedded in the oesophagus, and fixed by double-wire hooks embedded in the walls, also as to the best method of endoscopically ascertaining the position of, and successfully removing, pins aspirated into the lower and posterior lobe bronchi. All would agree with him that these cases presented the most serious difficulties in removal, and constituted the most problems with which the endoscopist had to deal. In this country owing to ill fitting dental plates and the bad habit of wearing them during sleep, a considerable number of dentures had been accidentally swallowed—in some cases with disastrous results. Many such cases had been recorded. He hoped that the folly and risk of this habit would be brought home to the public through the opinions expressed at this meeting, also by means of the *post-mortem* specimens exhibited in that portion of the Pathological Museum associated with the Section.

He referred to the case of a male phagm 1918 accidentally swallowed a portion of an upper dental arch two reversed hooks attached which became firmly lodged in the anterior wall of the trachea to the air passages may be free. Eight weeks after the flow of secretions on attempts to swallow, failure to find he obstructed oesophagus. (2) erosion of the wall was invited to through the oesophagus into the trachea, and denture—which inflicted on the larynx during attempts at removal, while it was or instrumental, the foreign body still being present. While it was

Diagnosis is by x-rays, first without then, if oesophageal with a capsule filled with an opaque mixture. If so postpone like coins always lie with their greatest diameter in the coronal plane of the body when in the oesophagus, or later sagittal plane when in the trachea. Lateral, or the posterior, and sometimes also quartering radiographs are necessary. One taken laterally, low down on the patient's side of the shoulder, will often show a bone, attempts at the antero posterior exposure

removed. The *post-mortem* specimen was exhibited in the museum connected with this Section.

A similar case was admitted, the same year, to the London Homoeopathic Hospital, in which an upper denture had been impacted for three years in the oesophagus, 1½ inches above the cardiac orifice, being hung up in this position by two metal hooks curved in opposite directions. He (the speaker) was asked by Mr. Dudley Wright to attempt its removal, following previous attempts, not only by peroral endoscopy, but also through the cardiac orifice by gastrostomy. On passing the oesophagoscope the denture, with the mesor teeth pointing upwards, was easily seen, and was grasped by forceps but it could neither be moved nor turned in any direction. The cutting shears at that time were too short to reach the denture, and the case was postponed until a longer pair could be made. The patient however refused to return to hospital for a further attempt at extraction, and died three years later from a post-mediastinal abscess caused by ulceration and perforation of the gullet wall.

Dr. Irwin Moore said he would be glad of any suggestions from Professor Jackson for dealing with such difficult cases. Next he referred to a case recorded by the late Mr. Hunter Tod in 1917, before the Section of Laryngology, Royal Society of Medicine.

A child, aged 12, accidentally swallowed (inhaled) a pin 1½ inches in length, which was located by x-rays in a lower posterior lobe bronchus. Systematic examination of the bronchi with the bronchoscope failed to find the pin while under control of x-rays and the fluorescent screen in the antero-posterior position the tube was seen in close contact with the pin and the latter within the grasp of the forceps, yet the pin could neither be seen nor removed. A lateral x-ray view showed the tube and forceps some distance away from the pin. Fortunately the pin was coughed up eighteen months later.

He (the speaker) would like to learn from Dr. Chevalier Jackson the best method, in his experience, of locating by means of the bronchoscope and x-rays foreign bodies in this situation. He differed from the opinion expressed in 1923 by Dr. Chamberlain of Cleveland, Ohio—in a discussion on a paper read by Dr. Ellen Patterson, entitled "Foreign bodies in the respiratory tract and oesophagus"—that the larger number of foreign bodies discovered in the lungs in America, in comparison with those in this country, could be accounted for by the fact that they did not look for them, and by the more thorough way in which they were searched for in that country by x-rays. This implied that a large number of foreign bodies were overlooked in this country, which, however, did not appear to be the case. That unilateral affections of the lungs—for example, bronchitis and localized bronchiectasis—strongly suggested the presence of a foreign body was well known to every endoscopist. He would admit that in some cases, especially in children suffering from unilateral affections of the lungs, and treated by the general physician, the question of a foreign body being the causative factor was not sufficiently considered, and was possibly overlooked altogether. He advised that more attention should be paid by the physician to the possible presence of a foreign body in all cases of lung affections, and that greater consideration should be given to the physical signs, and a more thorough examination made with the x-rays, and in doubtful cases with the bronchoscope.

MR. HERBERT TILLEY (London) said he had listened with much pleasure to the brilliant demonstration of Dr. Chevalier Jackson, and perhaps the detailed consideration of one case of his own might help to emphasize certain important points. The case was that of a little boy who inhaled into the left bronchus a paper-fastener with the extended wings lying upwards. A consideration of the immediate and later symptoms, together with the treatment accorded to them, illustrated some of the pitfalls which might lead to the overlooking of a foreign body, and the steps which should be taken in an endeavour to avoid them.

On October 2nd 1920 J.H. aged 5 swallowed a paper fastener. A violent fit of coughing immediately occurred and lasted about five minutes. This was accompanied by pain in front of the left chest which persisted off in some three hours. Four days later while at a children's party, such an alarming fit of coughing came on that the child's father and doctor were sent for and the patient was taken home. He remained in bed for a month with symptoms of acute bronchitis of the left lung. As these did not clear up a skigram of the chest was taken on November 29th but the result was so imperfect that it afforded no clue to the cause of the trouble. From that date to the removal of the foreign body the father stated that the child was always bronchial and short of breath, and the noise he made at night was like an passing

through a small hole." On different occasions he would "suddenly get cold and the temperature rise as high as 104° the attacks sometimes ended with vomiting followed by a sound sleep then all would be well again until similar symptoms reappeared." In June 1921, his tonsils, which were much enlarged, were enucleated, because it was thought that they kept up the bronchitis," but the chest symptoms were in no way benefited by the operation.

Since August, 1921, the attacks of pyrexia occurred every two or three weeks and especially after any exertion such as walking, in the meantime the appetite was failing and milk became the favorite food. A further consultation was held and the question of removing the appendix was discussed. During June, 1922, the child was so far from improving that Dr. Batty Shaw was then asked to see him. The chief physical signs which he found in the patient's chest were: expansion of the chest very poor, nearly all breathing being done by the diaphragm. The right chest however expanded a little, but the left especially in the lower part in front collapsed on inspiration, moreover, the left lung behind was dull on percussion vocal fremitus was normal, and I heard a rale on two.

In view of the history of the case and that the physical signs were chiefly located in one (the left) lung, Dr. Shaw advised that the chest should be screened" and Dr. Salmond's services were enlisted. He clearly demonstrated that the foreign body was lodged in the left bronchus with the chips fully spread and pointing upwards. The *corpus delicti* was removed next day, and the facts just recorded, together with some operative details were published in the BRITISH MEDICAL JOURNAL of November 1st 1922.

The lessons to be learnt from this story were the following:

1. The chief reason why the case drifted on after the initial accident was because the chest was not radiographed by an expert directly the trouble occurred. The first skiagram was made nearly a month after the initial symptoms, and then it was so defective that the physicians in charge of the patient were put off the scent and lulled into a sense of false security concerning the cause of the trouble. Not till twenty-one months had elapsed was a second screening made, this time, fortunately, by Dr. Salmond, when the foreign body was clearly demonstrated. During that interval of time the boy had had his tonsils and adenoids removed because it was thought they were the cause of the recurrent attacks of pulmonary symptoms with pyrexia, and he narrowly escaped being deprived of his appendix, which was deemed responsible for increasing malnutrition and indefinite abdominal symptoms. It might therefore be stated that a defective radiogram might be a positive danger rather than a help in diagnosis, and conceivably that a good one would often be invaluable.

2. The clinical history also emphasized the fact that the examination for the cause of chronic pulmonary symptoms, especially in a young child, could not be considered complete until the chest had been screened by an expert radiologist. This would be more than ever advisable if the physical signs were predominantly unilateral. Mr. Tilley wondered how many cases of bronchiectasis, recurrent attacks of "bronchitis," "pneumonia," "tuberculosis without tubercle bacilli," and "chronic cough" had been caused by the presence of an overlooked foreign body. He had reported such cases in the *Lancet* (November 7th, 1908, and April 22nd, 1911).

3. It might be asked, "Could radiography be of any value in diagnosis when the foreign body was not opaque to the x rays?" It might be so, and in this way. If the chest was screened at the moment of full inspiration and again on deep expiration, a comparison of the two negatives would often show a striking difference between the lights and shadows produced by expansion and contraction of the lungs, and a lack of the normal difference between these phases in the affected lung. This should at least arouse the suspicion of the physician, and lead him to consider the advisability of direct tracheo-bronchoscopy.

4. The physical signs recorded by Dr. Batty Shaw, and especially his reference to the fact that the lower front part of the left lung "collapsed on inspiration," should in this case have suggested to the earlier medical attendants of the child that there probably was some definite obstruction in one of the main bronchial tubes on that side.

With regard to foreign bodies being overlooked in the oesophagus, Mr. Tilley had only time to say that they might easily be missed: (1) when they did not cause much or any difficulty in swallowing, (2) when they were sufficiently large and of such a shape as to cause more difficulty of breathing than of swallowing, and hence were liable to mislead the physician as to the seat of

trouble, (3) cough might be produced by an oesophageal obstruction causing mucus to overflow into the larynx, and possibly only in this way, (4) an experienced endoscopist had often failed to find the foreign body when it had been in the cervical portion of the gullet because, if the head of the recumbent patient was overextended, the end of the tube would pass in front of and then beyond the obstruction. (A two shilling piece in his collection of foreign bodies had been missed in this way.) To obviate this possibility the head of the patient should be well flexed as soon as the end of the tube had passed beyond the cricoid narrowing into the upper end of the gullet.

Mr. F. B. WAGGOTT (London), after paying his tribute to Professor Jackson's monumental achievement, maintained that no examination for suspected foreign body was complete without a skiagram taken in the right antero-lateral position. In order to emphasize the deep nature of direct antero-posterior skiagrams he passed one round which, though clear and well defined, showed absolutely no trace of abnormality in spite of the actual presence of an exceptionally massive piece of bone lodged behind the manubrium sterni (fragment of sheep's vertebra exhibited, measuring $1\frac{1}{2}$ by 1 by $\frac{4}{5}$ inches, swallowed in his soup by a soldier of 20, who recovered after oesophagotomy). In well developed adults lateral skiagrams of the chest were often obscure, but those taken in the right antero-lateral position revealed not only small and comparatively transparent foreign bodies, such as bone fragments lodged in the gullet and trachea, but also those which were completely transparent, such as masses of meat and vegetables, the outlines of which were defined by the ingestion of barium or bismuth salts. The same method was employed in diseases of the gullet and trachea.

Mr. D. A. CROW (Brighton) said they had listened with enjoyment to men of very great distinction, there did not therefore seem any great reason why a junior surgeon should speak, unless it was possible that a brief account of early difficulties while they were fresh in his memory might serve to encourage some of his contemporaries, and profitably remind his seniors of stumbling blocks which they had encountered and had now forgotten. In his own short experience the laryngologist had been overlooked more often than the foreign body, the foreign body had been recognized, even demonstrated by a radiogram, and then left untreated. In the fullness of time the laryngologist would be offered a full responsibility in these emergencies. Secondly, these foreign body cases were rare, and their very scarcity made them difficult. In a hospital practice which provided him with about 500 operations a year, Mr. Crow had only been asked to deal with 8 cases of foreign body in two and a half years (two coins, two bones, one piece of meat, one piece of glass, a safety-pin, and a cherry stone). These were successfully dealt with except the cherry-stone, for the removal of which there was no adequate equipment at the time. The patient died. Infrequency of cases was a test of the endoscopist's patience and resolution, for the maintenance of equipment in a state of perfection and oneself in a state of constant practice, with the slenderest chance of being called upon to deal with a case, demanded of the surgeon an almost quixotic attitude of mind, in addition to a reckless expenditure of money and energy. Yet this difficulty of the scarcity of cases was a little compensated by the frequency with which they were called upon to perform oesophagoscopy in cases of suspected malignancy. This was a procedure well worth while, both from the patient's point of view, in that a confident negative opinion would give him great ease of mind, and from the point of view of the surgeon, who had had one more opportunity of acquiring skill and confidence. Thus it happened that the passage of the instrument, so easy in theory and so difficult at the outset in practice, became after a while a matter neither of doubt nor anxious concern. Many times, less than a year ago, he had failed to get past the cricoid constriction. There was a stigma in the experience of the endoscopist when for fear of doing harm, he proceeded with altogether excessive gentleness, and unless that stage was passed through there did not seem hope for a high success in his

ultimate work. Another difficulty had been the impossibility of forming a permanent team in hospitals, where of necessity residents and nurses were not permanently appointed. Much energy was expended in searching for and training fresh helpers every few months. Though he was conscious that he did not express the general feeling in this country, he did not find it easy to escape from the logic of the permanent team and the concentration of cases amongst a few well chosen and well equipped men, when he reflected, first, on the scarcity of cases if widely distributed, and secondly, on the unnecessary reduplication of the mistakes which inevitably occurred in the early experience of anyone undertaking this difficult work, nor could he imagine anyone who had seen team work in Professor Jackson's clinic remaining unconvinced to this view. In the three years 1921 to 1923, 147 fatal cases of foreign body occurred in Great Britain. The small number of fatal cases testified to the efficiency of British endoscopy, but the fact that there were any fatal cases at all conveyed the impression that there might be a wasteful diffusion of experience among many men, not all of whom were able to use it with profit.

A scheme for the training and appointment of an endoscopist for each county would, at this moment, have a rather absurd air of impracticability about it, and would by no means recommend itself to any of them, but until the need was greatly appreciated, surely certain laryngologists should be looked to in each district as men specially qualified for endoscopy. The remainder would be only too glad to be relieved of work for which they might have no particular taste, but which they were forced into doing by an uneasy sense of duty. There in this country had also an apprehension of the narrowing effect of extreme specialism, but he was persuaded that narrowness of vision was a congenital, not an acquired, defect, and that the specialist who ended up with a narrow outlook had just the same narrow outlook before he became a specialist.

Mr G. Ewart Martin (Edinburgh) said that he felt it a great honour to be asked to follow in discussion his friend and teacher Dr Chevalier Jackson. They had listened with much enjoyment to his great exposition. His work on endoscopy had stimulated them in this country, and they could only hope to follow him in a poor way, and carry out his suggestions and methods. Mr Martin was sure, however, that there was less opportunity of using the bronchoscope here, probably because its uses were not generally taught or widely enough known. In the hospital clinics in this country a case with a foreign body in the bronchus was rarely seen—so rarely, in fact, that he was forced to believe that in affections of the lungs the possibility of there being a foreign body present was too often forgotten, and the x-ray and the bronchoscope were too infrequently used in diagnosis of such cases. He could not believe that in the States, especially in Pennsylvania, whence Dr Chevalier Jackson drew a great many of his cases, children were more apt to inhale foreign bodies than in this country. It might be so, but Mr Martin thought it was much more likely that there the foreign body was much more sought after.

In Edinburgh, in the last eighteen years, they had records of only eleven cases where foreign bodies in the lower air passages had been diagnosed, and removed or coughed up. However, there were other uses of the bronchoscope than for the diagnosis and removal of foreign bodies, and it was here that they got the experience the necessity for which Dr McCrue had impressed on them. During the last three years they had been interested in its use in the diagnosis and treatment of certain affections of the chest. That the bronchoscope could be used in diagnosis of conditions of the chest was not fully recognized. The diagnosis of bladder and renal diseases was not completed until the cystoscope had been passed and an interior view of the bladder gained, along with the ureteral openings. Similarly, in obscure conditions of the chest, the bronchoscope should be employed to obtain a view of the inside of the bronchi and the openings of the smaller bronchioles. They had been using it for diagnostic purposes, especially in a Ministry of Pensions Hospital, among cases suffering from chronic chest affections many of them following the inhalation of

poison gas. It had been very interesting to note the physician's difficulty in coming to a definite diagnosis in these cases. Among cases diagnosed as bronchitis following gassing, no infection of the bronchi had been found, but there was present a very marked lower tracheitis. In others diagnosed as bronchiectasis there was found a simple chronic bronchitis with peribronchial thickening, the bronchi being practically immobile. Most interesting still, in the bronchoscope they had found a means of treating bronchiectasis, and very satisfactory results had been obtained by lavage of the bronchiectatic cavities through the bronchoscope. Mr Martin had been using the aspiration method suggested by Dr Chevalier Jackson, with the addition of boric lavage, passing the suction bronchoscope down to the mouth of the cavity, through this a two-way cannula was passed into the cavity, aspirating with the suction pump. After that, boric solution was injected through the second cannula, and the cavity then washed out. In some of the cases he had finished by painting the cavity with absolute alcohol. By this means there was set up a slight irritation of the cavity walls which tended to their adhesion. At the same time a spasm of coughing was set up, and this ensured that no purulent secretion was left above in the bronchus. Mr Martin gave a brief summary of a few cases.

Case 1—A D, a male with a history of definite bronchiectasis, coughing, and vomiting after food. There was a fusiform dilatation of the left posterior small bronchus extending for about 1½ inches, and 1 inch in diameter. About 2½ ounces of pus were sucked out with the first lavage. This was repeated a month later and again on four separate occasions with an interval of a month to six weeks between the treatments. The patient was fit to return to work and had put on 3½ st. The cavity was practically reduced to less than an inch in size and the cough had disappeared.

Case 2—J R, aged 24, admitted to hospital with bronchiectasis following pneumonia. Here again the left posterior bronchus was affected. There was a small spindle-shaped cavity washed out, which bled freely. Lavage was carried out on four occasions between the first and second occasions there was an interval of three weeks between the second and third occasions an interval of five weeks and then an interval of one month between the last two occasions. The cavity was very much reduced in size. There was still some cough and sputum but no odour.

Case 3—Miss G. had a ten years history of bronchiectasis following the inhalation of a tooth. On bronchoscopy there was seen a large cavity on the right side fairly far out. No signs of a tooth could be found nor was there any sign in a previous radio gram. Lavage had been carried out on six occasions at varying intervals usually of three weeks to a month. There was now practically no fetor from her breath, no sputum and she had put on weight and felt very comfortable. Unfortunately in this case after the last two treatments though the cavity had been found to be very much reduced in size, there had been a good deal of bleeding and haemorrhage following the lavage, rather alarming to the patient.

Case 4—G N, aged 50, admitted with left sided bronchiectasis. A bronchoscope was passed down to the division of the small bronchi. There was no coughing up of pus until this was reached. The mouth of the posterior small bronchus was poulticed and on passing lower there was an immediate gush of very foul pus. The cavity was then distinguished and washed out with boric solution. The lavage was repeated on three occasions with an interval of three weeks between the first and second lavages and a month between the last two. On the last occasion the cavity could not be distinguished and there was no pus or sputum. Two months later unfortunately when at work the patient developed pneumonia on the right side from which he died but curiously enough there was no extension of the pneumonia to the previously affected side and no coughing up of pus during the pneumonia.

Case 5—A boy aged 17 on examination showed the right side of the chest completely dull. The x-ray examination showed complete dullness of the right side. Various attempts had been made to tap the chest by needling all failing. The case was diagnosed as a lung abscess. With suction bronchoscopy the chest was quite easily emptied about 6 ounces of pus being drawn off but no definite cavity formation could be made out owing to the congestion of the whole of the right bronchus. The boy was better next day but the improvement did not continue. An external operation was then suggested as it was thought that with the bronchoscope we could not hope to be successful. The boy unfortunately collapsed during the anaesthetic before the external operation.

Altogether Mr Martin had had the opportunity of treating 14 cases of bronchiectasis. Of these 1 was a definite failure, 2 showed very little improvement and he did not continue with the treatment beyond the second time, 4 cleared up completely, 2 were clearing up and would probably only need one or two aspirations; the others were at present under treatment and showing improvement. He

had found that between the first and second lavages an interval of only two or three weeks should elapse, between the second and third lavages an interval of three weeks to a month, and after that an interval of one month. Bronchial lavage was preferably carried out under a local anæsthetic, the pharynx and epiglottis being sprayed with less than 1 ccm. of a 10 per cent solution of cocaine (in children 5 per cent). Under a general anæsthetic bronchial lavage had been found difficult and at times a rather alarming, and he did not think it advisable. In one of the later cases, a child of 12, he tried the second lavage under a general anæsthetic, the previous lavage having been done under local anæsthesia, he was very much happier with the local anæsthetic than with the general anæsthetic. The initial bout of coughing brought up a large amount of pus which was inhaled, and the condition and colour of the patient gave rise to continual alarm. In this form of treatment there was a hope of benefiting those bronchiectatic cases which in the past had gone on for long periods, a nuisance to themselves and to their friends, in their continual coughing and unpleasant breath. The possibility, of course, of a foreign body being present should never be overlooked, for this, more often than not, was the origin of the bronchiectasis. With the use of a distal lighted bronchoscope, and the examination so easily made, a means was offered of diagnosing and treating conditions of the chest which in the past were left untreated and only theoretically diagnosed.

Mr MUSGRAVE WOODMAN (Birmingham) described two cases which came under the category of overlooked foreign bodies in the oesophagus, and showed lantern slides illustrating them.

Case 1—A boy, aged 16, was admitted on the medial side complaining of vomiting and pain in the chest. No history of the ingestion of a foreign body was given (or asked for). The case presented some peculiar features and an x-ray examination revealed

the presence of an open penknife in the gullet. The sharp end of the blade was pointing downwards and removal was easy. Had the point presented upwards it would have been necessary either to close the knife *in situ* or to smother the sharp end of the blade with forceps.

Case 2—A woman, aged 23, was confined. Six weeks later she was removed to hospital and admitted with a diagnosis of post partum meningitis. She had a high temperature was conscious but in great pain, the outstanding feature of her case was intense rigidity of the head and neck. When the history was elicited she admitted having swallowed a large poultry knife fourteen days

previously. This was shown to be present on x-ray examination and appeared to be in the mid-thoracic region of the oesophagus. Under local anæsthesia a Jackson's tube was inserted rapidly down the oesophagus, which appeared to be empty. On retracing the route a small slit-like opening was found in the posterior wall of the pharynx immediately above the entrance to the oesophagus. The tube was then passed through this slit and entered at once a connective tissue zone full of pus and gangrenous granulations. It was passed downwards into the mediastinum and soon wandered in a maze of vessels in which localization was difficult or impossible. But no knife was found. An external incision had to be made and a gush of air indicated that the pleural sac was open. Fingers were inserted through the slit and the handle of the knife felt and removed. The patient subsequently died. The knife had entered the pleural sac near the apex, grazed the side of the lung and its point had entered the diaphragm. The striking point in this case was that in a moment of insanity the patient had

attempted suicide and, failing, had made no mention of the fact to her friends and she had actually wallowed about for fourteen days with the knife *in situ*.

Sir JAMES DUNDAS GRANT (London) said that among the foreign bodies with which he had had to deal three might certainly claim to have been overlooked—one for a year, another for twenty weeks, and a third for over eight months. The first patient had suffered from cough and fetid expectoration for about a year. Dr Perkins found dilatation of a bronchial tube, and a radioscopic examination revealed a safety-pin, which was extracted by low bronchoscopy. In the second a rabbit bone was supposed to have been swallowed. There was severe cough and copious expectoration of sweet offensive odour and of the colour at times of raspberry sauce. It was only after twenty weeks that he presented himself, and the x-rays showed an opaque spot at the level of the fourth intercostal space anteriorly (and of the eighth rib posteriorly) suggestive of a foreign body. He had already developed clubbing of the fingers. By superior bronchoscopy Sir James Dundas Grant was able to see the foreign body and to extract it along with the bronchoscope by means of Killian's forceps. The third was a boy who was taken suddenly ill with vomiting, pain on the left side of the chest, and a good deal of cough which soon subsided. He recovered sufficiently to go to the country, but eight months later, after a period of comparative latency, was found by Dr Perkins to have collapse of the left lung. He referred the patient to Dr Melville for x-ray examination, who found at the level of the left bronchus a shadow characteristic of a collar-stud. The speaker was unable to introduce a sufficiently large tube through the larynx, but through a high tracheotomy opening he was able to remove the collar-stud by means of a short bronchoscope. He asked Professor Jackson whether he had been able to utilize lipiodol or bismuth in the detection of foreign bodies which were not opaque to the Roentgen rays. He congratulated Professor Jackson on the wonderful power of endurance displayed by him in this lecture demonstration, and assured him that he was probably the only one who could have invited the attention of the large audience as he had done.

Dr PATRICK WATSON-WILLIAMS (Bristol) said that while associating himself with the warm gratitude to Dr Chevalier Jackson, so eloquently expressed by Sir StClair Thomson, he did not propose to refer to his own relatively small experiences in bronchoscopy, but would touch on Dr Jackson's explanation of the different pulmonary symptoms in cases of (1) nearly complete bronchial occlusion—for example, by a per-nut or bean causing emphysematous dilatation of the corresponding lobes—and (2) complete bronchial occlusion resulting in atelectasis. These different results, due to such slight difference in obstruction, Dr Jackson explained, were due to dilatation of the bronchus on inspiration and contraction during expiration, which in incomplete obstruction allowed inspired air to enter but caused it to be locked in on expiration, while with complete obstruction no air could enter and what was beyond the occluding bean became absorbed, hence atelectasis. This dilatation and contraction of the bronchi, and its very important bearing on medicine and surgery in relation to chest affections, Dr Watson Williams had described and stressed in a paper in 1903,¹ and he believed it was the true explanation. But Dr McCrae had drawn attention to the value of unilateral deficiency of chest expansion as an indication of foreign body in a bronchus, which from its position or size was incapable of causing obstruction, and Dr Jackson's reference to the obstructing per-nut could not possibly apply in the conditions described by Dr McCrae, or afford the explanation of Dr McCrae's sign, which was of such import in cases of non-opaque non-obstructive foreign body in a bronchus. The speaker believed that the explanation lay in the neural inhibitory effect on the normal dilatation and contraction of the corresponding bronchus that the presence of the foreign body exercised, and that in such conditions dilatation on inspiration was below normal, and hence the corresponding lung was expanded less than that on the normal side, despite the absence of any obstruction.

BRONCHOSCOPY FOR DISEASE *

BY

CHEVALIER JACKSON, M D, So D, F A C S

In suppurative conditions due to foreign body abundant experience has demonstrated that no procedure other than bronchoscopy is worthy of a moment's consideration. In suppurative conditions due to causes other than foreign body the status of bronchoscopy is altogether different, it is merely an adjunct to the medical and surgical care of the case. Both the physician and the surgeon have found a bronchoscopic assistant of great usefulness in diagnosis and in treatment of certain classes of cases.

Pulmonary Malignancy

Malignant disease of the lung is a mild, and for a long time purely local, process. The bronchoscope is the only means by which an early diagnosis can be made with the certainty required by the surgeon. When the bronchoscope is resorted to early, a positive diagnosis of primary pulmonary malignancy enables the surgeon to cure by lobectomy. One of the most striking things in bronchoscopy for disease is the frequency with which the bronchoscopist finds unsuspected cancer in a patient treated for months, even years, for a supposed benign or tuberculous suppuration. We think every case of haemoptysis in which no tubercle bacilli can be found should be bronchoscopically examined for diagnosis.

Suppurative Pulmonary Disease not due to Foreign Body

Hippocrates and his predecessors preached drainage of suppurative areas. Throughout the centuries since the days of Hippocrates this has remained the unshaken foundation of all surgery of suppurative disease. The only modern thing is the discovery of the feasibility of drainage through the mouth. The question therefore is, How efficiently can we drain suppurative areas in the lung with the bronchoscope? So far as experience up to the present is an indication we may answer. In a few cases it is hopelessly inefficient, in other cases curatively efficient, in most cases, stagnation is prevented, the odour disappears, and the general and local conditions improve. Until 10,000 cases small furnish data for analysis it will be impossible to classify cases beforehand as to indications for bronchoscopy. Of bronchoscopy for suppurative disease of other than foreign body origin we can only say positively that we can safely and successfully combat stagnation in the bronchi. It becomes a question, then, of how great a factor endobronchial stagnation is in the perpetuation of pulmonary suppuration.

Let us consider for a moment the normal physiological mechanism for the prevention of stagnation of any excess of secretion in the bronchi, large and small. There are three mechanical factors—namely, (1) the "squeeze" of thoracic compression of the lung in cough, (2) the cough blast, (3) ciliary action. Upon the efficient and co-operative activity of these three factors drainage of the human lung depends. A chain is no stronger than its weakest link, and the weakest of the three links in this chain is the ciliary link. It is not at all certain that the ciliary link is the weakest under normal or mildly pathological conditions—in fact, my personal opinion is that it is the most efficient of the three—but I am equally convinced that the ciliary link is the first to weaken and break down in the presence of gross inflammatory changes in the mucosa of bronchi, large and small.

To be convinced of these two statements one has only to see the stream of pus distributed along the posterior wall of the bronchi in recent suppurative conditions of mild degree, evidently an upward flowing stream, and to compare it with the stagnant pool or adherent patch of stale or foul pus in chronic conditions. Considering the structural delicacy of the cilia it is logical to suppose—and the supposition is supported by histological studies—that violent or long-continued inflammatory processes destroy the cilia or impair their activity in the area affected. Then enters

another factor to impair ciliary activity—namely, obstruction due to inflammatory swelling of the mucosa, which, as all bronchoscopists have seen, objectively obliterates the smaller bronchi. Still another factor to impair ciliary efficiency appears if the inflammatory process continues and the already impaired ciliary action is not aided—namely, the development of granulations. The subjacent impaired, or even unimpaired, cilia, if such exist, cannot do much in the way of forcing pus through a bronchus whose lumen is completely occluded with granulations dovetailing together in their mutual approach from opposite positions in the bronchial wall. And, moreover, it must be noted that granulations have no cilia. Hence, a granulating area creates a gap in the continuity of ciliary effort. A ciliun, like an individual in the line of a bucket brigade, can pass on only what is received from the adjoining co-worker. The unreplaced dropping out of a number of individuals in the line stops the transmission. This in the bronchi means stagnation, and we may say that stagnation is one of the chief factors in the development of pulmonary abscess and of bronchiectasis.

Bronchoscopic Aspiration

The pathological considerations referred to in the foregoing paragraphs give us an explanation of the remarkable results obtained, clinically, from bronchoscopic aspiration in certain cases. These results have amply justified the statement that the bronchoscope is the most efficient means yet discovered of combating stagnation of pus in the bronchi. The larger bronchi are quickly emptied with the aspirator. The "squeeze" of the thoracic compression of the lung during cough forces up the pus from the bronchioles and obstructed smaller bronchi, and the multiple minute pockets, into the larger bronchi, whence the aspirator can readily remove the pus.

Multiple foci of suppuration deserve separate consideration. Usually the separate foci can be reached in turn by the aspirator. If not, however, they may be fairly well drained by the squeezing due to the compression of the whole lung by the cough. This mechanism is endoscopically obvious during bronchoscopy in suppurative cases. The visible pus in the larger bronchi is removed by aspiration, and the bronchi are for a moment visibly clear of pus. The next cough forces up a quantity of pus from certain bronchi or fistulae. This in turn is aspirated. The next cough forces up more pus, but the quantity is less. This is aspirated, and is replaced by a still less quantity. This cycle is repeated until all the communicating cavities and fistulae are clear.

Summarizing, it may be stated that in any case of suppurative focus communicating with a bronchus, and in which the surgeon and the internist deem external operation not strongly indicated, bronchoscopic aspiration should be used to supplement medical care. A very satisfactory percentage of such cases will be cured. The chief contraindications to bronchoscopy are (1) a moribund condition of the patient, (2) imminent rupture of the focus into the pleura.

Suppurative Foci not Communicating with a Bronchus—These can be penetrated with the bronchoscope if deemed advisable, but the wisdom of doing so has not yet been demonstrated. If for any reason the surgeon deems external operation inadvisable, bronchoscopic penetration may be considered. In such cases spontaneous rupture into the bronchus or the pleura usually occurs sooner or later, and delay in external operation is very rarely advisable.

EVOLUTIONARY FACTORS IN THE PRODUCTION OF PHARYNGEAL DIVERTICULA

BY

V E NEGUS, M S, F R C S

(Abstract)

MR NEGUS commenced by describing the site of exit of the pouches under consideration as between the lowest circular and adjacent oblique fibres of the inferior constrictor muscle of the pharynx. He referred to the importance of longitudinal muscle fibres in pulling the pharynx and oesophagus

* Abstract of chalk talk and cinema demonstration.

over a bolus of food, in much the same way as that in which a snake appears to creep forward over a rabbit when swallowing it.

The obstructing action of the powerful and tonically contracted crico-pharyngeus muscle was pointed out, and the function of the muscle was described as one related to the necessity for prevention of an entrance into the oesophagus during inspiration, in order to ensure its passage into the lungs. This function was said to be most important in those animals with a narrow laryngeal aperture and in those which close the glottis when the thorax needs to be fixed during independent use of the fore limbs.

The function of the cartilages of Santorini was given as that of suspension of the oesophagus, in such a way that when the larynx is closed for deglutition the oesophagus is opened in a funnel-like manner.

The absence in man of longitudinal muscle fibres in the posterior part of the pharynx at its lower end was compared with the condition in various animals.

The role of the posterior palatine folds was spoken of in relation to olfaction and deglutition, especially with regard to direction of food into the mouth of the oesophagus, and it was pointed out that keen-scented animals have strong folds in close relation to the larynx, and that most herbivorous species have a complete girdle called the arcus palato-pharyngeus, made up of these palatine folds united posteriorly.

It was shown how descent of the larynx in the neck of man for various reasons has led to fanning out of the inferior constrictor muscle.

The reasons why pharyngeal diverticula do not occur in various types of animals was compared with the condition of man, in whom the predisposing factors were given as these. First, descent of the larynx and fanning out of the inferior constrictor muscle, associated with absence of longitudinal fibres in the lower pharynx posteriorly, so that during swallowing upward pull of various muscles and downward pull of the oesophagus cause stretching in the position where a diverticulum arises. Secondly, lack of relaxation of the crico-pharyngeus muscle because of delayed passage of an excessively large bolus. Thirdly, absence of directing posterior palatine folds because of the degeneration of the olfactory sense and the lack of necessity for combined respiration and deglutition. And lastly, attachment of the oesophagus in part to the cricoid cartilage, and not entirely to the cartilages of Santorini, with the result that funnel-like opening is not efficient.

MEDICAL, SURGICAL, OBSTETRICAL

ACUTE APPENDICITIS IN AN OCTOGENARIAN

Cases of appendicitis in patients over 80 years of age must be rare.

Mrs P., aged 86, suffered from acute abdominal pain late one afternoon. Dr Owen Foulkes Evans was called in and suspected acute appendicitis, the temperature was slightly elevated. Next day she was worse, and I saw her in consultation and found great abdominal tenderness in the right iliac fossa and rigidity, the temperature was 100° F. It was now definitely a case of rapid acute appendicitis. She was operated upon twenty-two hours from the commencement of the symptoms, and we found, immediately under the parietal peritoneum, a large, green, distended appendix showing a pale area at one spot, the appendix was evidently on the point of bursting. On removal it was found to be full of stinking material, and the whole was gangrenous. There was some turbid material in the pelvis. She made an uninterrupted recovery. The wound was not drained.

W. THELWALL THOMAS

RECTAL INJECTION OF TARTAR EMETIC FOR BILHARZIASIS

Since reading, at the time, the article by H. F. Wilson of Livingstonia, Nyasaland, published in the *BRITISH MEDICAL JOURNAL* of January 28th, 1922 (p. 137), giving the results of his treatment of bilharziasis by rectal injections of tartar emetic, I have, since that date, and in consequence of reading that article, used exclusively that treatment.

I commenced, as he did, with graduated doses, but ultimately came to the conclusion that a single dose, large enough to destroy the parasite, was the only rational treatment for this disease.

I have given as much as 19 grains in one dose, without unpleasant effect. But this was not given as a first dose, neither was it given to a case of bilharziasis. I have not given a larger dose than this, because 19 grains is so much in excess of the minimum dose universally lethal to the parasite that to experiment with larger doses seems useless. The last case I treated, a native boy of about 17, had but one injection, of under 6 grains. After this injection the ova disappeared.

I dissolved the weighed dose of tartar emetic in four ounces of warm water, and injected with a four ounce all-metal ear syringe, over whose metal nozzle had been drawn the soft rubber conical end-piece shown in Down Brothers' catalogue, as No. 1683, on p. 389. With vaseline applied to the anal canal, the insertion of this soft rubber end-piece is easy. I think half an hour in the recumbent position, after the injection, is sufficient, and have been indifferent as to whether the bowel was emptied previously or not.

The simplicity, safety, convenience, and efficiency of the rectal administration of tartar emetic appear to make its intravenous injection in bilharziasis no longer a justifiable treatment, and they further appear to open up new possibilities in the direction of eliminating human schistosomiasis from any district. Whether the routine injections towards that end should be given every seventy days, or at some other interval, will have to be decided by further experiment.

J. BARCROFT ANDERSON, M.D., D.P.H.

London.

TORSION OF A LARGE DERMOID OVARIAN TUMOUR

THERE were some circumstances in the following unusual case of a dermoid ovarian tumour which are of interest.

A single woman, aged 39, a cook, was exceptionally uncommunicative towards her mother and sisters, and never discussed her health with them. She resolutely avoided medical advice.

When first seen at 9 p.m. on June 19th the abdomen was enormously distended and she was acutely ill. She said that for the last ten years she had noted a fullness and swelling of the abdomen which had gradually increased, but although she had lost weight recently she had carried on her work and even cycled up to seven days before.

On June 10th, preparatory to a day's excursion in a car she said she had laced her corsets extra tightly, and that she had been jolted about because she had been seated on the floor of the car on the return journey. She felt very ill that evening and suffered thereafter from severe vomiting and diarrhoea coupled with rapidly increasing abdominal distension. It seemed almost incredible that the abdominal wall could stand the tension existing, the temperature was 102° F. and the pulse rapid. She was immediately transferred to Cirencester Hospital, where she was operated on at 11 p.m.

The tumour was exposed through a left paramedian incision and was found to be markedly adherent to the parietal peritoneum. The wall of the tumour was a quarter of an inch thick and densely adherent to it were most of the coils of the small intestine and great omentum. An incision released approximately 4 quarts of yellow pulaceous fluid. The tumour arose from the left ovary and had undergone torsion; it was removed. The patient stood the operation well but died four days later.

The tumour was exceptionally big, weighing, after the loss of the 4 quarts of fluid, 18 lb., which makes the total weight approximately 25 lb. It was multilocular and contained masses of yellow pulaceous material mixed with hairs, together with portions of bone, cartilage, and fibrous tissue.

The remarkable feature of the case was the small interference this huge tumour had produced and the way in which the patient had even cycled until seven days before the operation.

The rapidity of the final enlargement was another astonishing feature, and the provisional diagnosis when she was first seen, of an ovarian tumour with torsion of the pedicle causing oedema of the tumour, seems to be the best explanation of the chain of events.

OSTEOPATHY, CHIROPRACTIC, AND MEDICINE

At a crowded meeting of the Medical Society of London on October 12th, Sir HOLBURN J. WARING was inducted in the chair of the society by his predecessor, Dr E M CALLENDER, and delivered his presidential address, taking for his subject "Osteopathy, chiropractic, and medicine." The address is printed in full at page 679. After a vote of thanks had been recorded, discussion was called for.

Sir STCLAIR THOMSON said that it was rather depressing to national pride to think that all these things seemed to arrive in England when they were dying out in their own country. It reminded him of what the Germans used to say, that Oxford was a place where German philosophy went when it died. These various cures led sometimes to confusing results, and he recalled a remark by Henry James, who, talking of the mind cure and the faith cure, explained that the difference between the two was that the mind cure required no faith, and the faith cure required no mind. The speaker told the story of a lady of the manor, a "Christian Scientist," who, meeting a little girl whose mother was ill, told her to tell her mother that she was not ill, but only thought she was. A few days later the lady met the child again, and the child, on being asked how her mother was, replied, "Please, ma'am, she thinks she's dead!" The president had suggested some methods of combating quackery, but the speaker feared that for his own part he was getting somewhat cynical. He called to mind the remark of Carlyle about the inhabitants of these islands, also a remark of Bishop Creighton, quoted by one speaker at the recent Church Congress, that although it might be true that the tiger and the ape in man had died, there was plenty of evidence that the donkey still survived. He had often wondered why these things were so popular in America and in this country, and apparently had no vogue in France or Italy, but in those Continental lands there were healing shrines and doubtless other forms of supposed cure which could claim remarkable results in functional disorders.

Dr DES VOEUX reminded the meeting that quacks had existed throughout the history of medicine. They would continue to exist, and he thought that as long as the medical profession could not cure all ailments quacks ought to exist. If they did any good they were a benefit to the public, and if they did any harm they were a benefit to the profession! When "bonesetters" first came in they "wiped the eyes" of many elect surgeons, and most medical men had experience of cases in which these persons had got rid of icks and pains and had cured people of their disabilities when the doctors had been unsuccessful. From what he had heard from his own patients the same thing was true of osteopaths by their manipulations they gave relief to reflex pains elsewhere. It would be most unwise for the profession to do anything to discourage this sort of irregular practice. He had known very many cases where such persons had done no good, but he had known very few cases where he could honestly say that they had done a great deal of harm, and at any rate it was a comfort to patients to feel that if the doctors could do nothing for them they could go to somebody else. There were people who had incurable cancers, and discovered some new flicker of hope by this recourse, and he did not think they should be discouraged. What he did dislike was quackery within the profession.

Dr E M CALLENDER did not agree. He had seen many sad cases in high positions in society. He knew of a case in which three children were allowed to die of tuberculous meningitis without any steps being taken to protect them from the disease other than "Christian Science" treatment. He had seen a family of children in a West End square treated by an osteopath for whooping-cough, and allowed to cough and vomit and lie awake at night with nothing done for them except the rubbing of their backs. One lady came to him to be treated for some other condition, and he noticed her cough, which was symptomatic of chronic bronchitis, but she told him that she did not want his treatment for that because she was being treated for it by an osteopath.

Mr J E H ROBERTS said that a few months ago he saw a case which had an interesting bearing on the discussion. It was that of a man who had had a bullet wound and other injuries in the war, and had suffered for some time from incomplete paraplegia, but recovered completely, and had had no ill effects for four or five years. At the end of that time he began work as a dustman, and on lifting the heavy bins got severe pain in the lumbar region. On x-ray examination it was quite evident from the lateral view that he had a subluxation of the second lumbar vertebra upon the third, the displacement forward being nearly half an inch, and he had bony changes in the articular processes. The bullet, which was lying harmlessly in the muscles, had nothing to do with the pain, but the bone displacement, the result of another injury, gave trouble when the man lifted heavy weights. With that kind of displacement, according to the theory of the osteopath, there should be compression of the nerves coming out from the intervertebral foramen, but the man had no pain at all from those nerves, nor did he develop appendicitis or carcinoma or any other fell disease. The speaker happened to meet an osteopath—a "D.O." of somewhere in America, who had also a British medical qualification—and said to him, "You say you can cure by osteopathy subluxation of the spine. Here is a condition which has been present for five years. Can you reduce it?"—and he showed him the x-ray photograph. "Oh," said the osteopath, "but that is a real subluxation! I should not advise you to touch that." It was very interesting to observe the attitude of the osteopath when confronted with a lesion which was demonstrable on an x-ray plate.

Mr WARREN LOW could not echo Dr des Voeux's eulogies, though he agreed that the profession should leave them alone. He did not think that a medical organization ought to take any notice of irregular practitioners, by prosecution or otherwise, but it was very necessary for medical men individually to keep clear of them, and it was a pity that any members of the profession should meet them, even occasionally, in consultation. Sir Holburn Waring's suggestion had been that some department of State should undertake the education of the public so that they might be possessed of sufficient knowledge of themselves to see through the claims of some of these persons. There was one group of cases in which sometimes the osteopath had his greatest successes—persons who had sustained some injury to the back and had complained of pain for a long time afterwards. The course of events depended a good deal upon the class of society to which such people belonged. If they belonged to the leisured class, with no financial interest in the continuance of their disability, they were cured quickly by the osteopath or got well of themselves. But the speaker had had to do with certain cases of men who got more or less of a living out of it, men who were perhaps hurt on the railway five years ago and had had pain ever since, and he had never yet found an osteopath who could cure them.

Dr E GRAHAM LITTLE, M P, said that the question of osteopathy would probably come up in the House of Commons quite soon as a consequence of the meeting held at the House six months ago. That meeting had been called by a number of members who were in favour of osteopathy, and was addressed by a qualified medical man who had for saken the ordinary practice of medicine for this new cult. All the medical members of Parliament attended the meeting, and after an hour's talk by the visitor each of them was allowed three or four minutes, after which they

were told that no further information from the medical point of view was required, and a resolution was carried. The ominous part of the business was the fact that it was the Ministry of Health which appeared to be most sympathetic to this movement in favour of osteopathy, and there was all the more need, therefore, for the medical profession to voice the opposition. He was in agreement to some extent, however, with Dr. des Voeux. There were cases in which the osteopath and the chiropractor, quite unwittingly, had done a considerable amount of good to the patient under their treatment, and occasional cases of this kind to some extent explained the remarkable vogue which these practices had acquired. The public had been severely blamed that evening by one speaker, but, after all, one should place oneself in the position of the patient who had been discouraged by the little that regular medicine could do in his case. He mentioned one case known to him of a man who had come from abroad to seek relief for a condition which affected his sight. He was sent in the first place to a neurologist, who examined him and said he could do nothing for him. Then he went to an oculist, who prescribed another pair of glasses which suited him less well than the pair he had been using. Finally he went to another neurologist who suggested an operation, but candidly explained that it might be of no use and might result in permanent disfigurement. The man paid the consulting fee of this neurologist, and forthwith put himself in the hands of a quack, who, by assiduous treatment, was at any rate making the man feel that he was getting better. The only success of what was called "bonesetting" should serve as a warning to the medical profession against taking too decidedly negative an attitude. In Parliament, where there was a feeling that jealousy on the part of the medical profession was confusing the issue, there would be quite a good deal of support for osteopaths.

Mr. HOLBURN WARRICK could not agree with Dr. des Voeux that irregular practitioners should be allowed. It was the duty of the Government to protect the citizens from fraud. With regard to Dr. Little's statement as to what had occurred in the House of Commons, he imagined that few members of the medical profession realized that there was really a definite proposal that osteopaths and chiropractors should be registered in this country. If this came about it would mean that there would be a considerable number of practically uneducated people placed in the position of treating all kinds of disease. In every State in America where the experiment had been tried, the so-called limitation of practice of the osteopath and the chiropractor had proved impossible to carry out. He was strongly of opinion that the frauds which would be possible here if osteopaths and chiropractors were licensed ought not to be permitted. It was a great pity if the Ministry of Health was the weak spot in the armour, but there was nothing to prevent the licensing bodies in the profession from discussing the question and deciding what measures ought to be taken. It would be disastrous if the osteopath and the chiropractor were licensed to practise.

DIFFICULTIES IN THE USE OF INSULIN

A discussion on "Difficulties in the use of insulin" took place in the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on October 13th.

Dr. GEORGE GRAHAM, President of the Section, in opening the discussion, said that on a similar occasion in the Section two years ago the main concern of the speakers was to show that insulin was a very great discovery, and that it could be used with safety, provided reasonable care was taken. In the two years which had elapsed it had been shown conclusively that insulin was a very potent drug. Some patients who were now under treatment looked and felt so well that no one would suspect them of having any disease so long as the food they were avoiding at meal-times was not noticed. The great majority of patients, if not quite so well as this, were immeasurably better than before the discovery of insulin and only a small minority remained invalid. But although the general position was satisfactory many points of difficulty arose in the technique of treatment. Dr. Graham analysed the group of patients in whose treatment he had taken a share at St. Bartholomew's Hospital during the last two years. These had all

been in hospital previous to 1925, and afterwards attended the out-patient department, the great majority of them every two or four weeks. Of 86 patients treated with insulin, 68 were still under treatment and 18 had died. This number of deaths seemed large, but on analysis there was evidence that in 12 cases another disease was present, which probably precipitated death. Of one case, however, which died in hospital, he gave a long account, the case had to be regarded as one of progressive degeneration of the islets of Langerhans in spite of adequate doses of insulin, and there was a second case which, he suspected, died (at another hospital) from the same cause.

With regard to the maintenance of the fasting value of the blood sugar within normal limits, among the patients he had treated in hospital or nursing home so far there had been only two with whom it was impossible to attain this ideal. He expected these two cases to do badly afterwards, but actually they were both alive and fairly well two years after treatment was started. One woman whose blood sugar in the morning before the insulin injection was never less than 0.18 per cent now had a blood sugar of 0.25 per cent; she took 35 units of insulin a day, and ate a diet representing 1,000 calories. At first she gained weight very rapidly, but now maintained her weight, and was capable of doing her housework. These two cases notwithstanding, he still believed it to be a great advantage to the patient if the blood sugar could be maintained within normal limits, provided no discomfort was caused. He had watched many patients in the out-patient department develop high blood sugars in spite of treatment, and had been able to measure the decrease in tolerance by the increase in insulin requirements. It was, however, impossible to say for certain that the downward progress would have been more rapid if the blood sugar had been allowed to remain high. He had tried in all his cases to keep the morning value of the blood sugar—that was, after an ordinary breakfast—below 0.13 per cent. If a patient receiving only one dose of insulin had a raised blood sugar in the morning the dose was increased by 2 units so as to avoid two injections a day, but if this increase caused signs of overdose at midday without lowering the morning blood sugar a second daily dose was clearly required. Originally it was advised that the evening dose should be smaller than the morning on account of the danger of hypoglycemia at night, but he had been forced of late to increase the evening dose in certain cases considerably above the morning dose. A case which suggested a smouldering tuberculous infection dealt with the increased evening dose, patients with tuberculosis usually developed pyrexia in the evening, so that the high evening dose might have been required to counteract the effect of the pyrexia. With minor infections which might cause a raised blood sugar in a diabetic patient, his plan was to increase the insulin by 1, 2, or 3 units as soon as the illness started. On any signs of overdose the insulin was reduced. If the infection was severe the urine should be collected as far as possible in three-hourly periods and tested for sugar, and the dose of insulin might have to be very largely increased. If, for example, the patient developed a carbuncle the actual dose of insulin might have to be over 200 units a day. The danger in these cases was, not in giving too much, but in giving too little. It required courage to increase the dose from 20 units to 200, but it could be done as the doctor gained knowledge and confidence in insulin treatment.

Adjustments of Insulin Dosage to Exercise

Dr. R. D. LAWRENCE referred to the changes in the dose of insulin rendered necessary by increased activity on the part of the patient. One of his cases was a gardener who periods of activity varied. He had been on constant diet for one and a half years, and had had 10 units of insulin in the morning and 6 in the evening. In the spring, when very busy with his work, troublesome symptoms of hypoglycemia showed themselves, and the insulin accordingly was reduced until 6 units once a day sufficed to keep his blood sugar at the same level as the two doses a day had done before. But on entering a rest period his blood sugar began to mount up, and soon he was passing sugar most of the day. His insulin was then raised to 8 units in the morning and 5 in the evening, and this kept him at the right level, but on

resuming his former activity he got hypoglycemia, and the insulin had to be reduced again. Another patient who ordinarily led a sedentary life played tennis at the weekend, and on a dose of 16 units of insulin in the morning and 12 at night, which kept him right during the week, he got serious symptoms of hypoglycemia within a few hours after his game. Eight units maintained him in the same condition when engaging in this exercise as 16 units had done when he was leading his sedentary life. This man went on a vigorous holiday, and, instead of lowering his insulin, raised his diet, doubling his carbohydrates, and was sugar-free all the time, and even got occasional hypoglycemia. To increase the food during activity rather than to reduce the insulin would be the more physiological way of proceeding, but it was rather complicated. With regard to infections, among the forty or fifty patients who came to him regularly at the hospital he had not had a case of serious infection, and had not noticed that colds in the head, save in one case, appreciably caused glycosuria.

Dr E P POTLON said he had found that the mild cases of diabetes did better with small doses of insulin than with dieting alone. He described one such case of long standing in which, before the patient suffered from giddiness on and this had disappeared when he was put on small doses of insulin. In very wasted patients there was a great danger in treating with insulin unless a large amount of carbohydrate was given. He also described one curious case which dated from the pre-insulin days. The disease started as a pancreatitis, with jaundice, and a mild diabetes followed. The patient was eventually treated with insulin, and the sugar tolerance curve remained more or less stationary. There was now, however, some slight degree of deterioration, and this patient had always the particular symptom of pain in the epigastrium and mild attacks of jaundice. Possibly, dissection of the gall bladder might be attempted, but it seemed a drastic thing to open it on these rather slight indications.

Canadian Experience

Dr C H BEST of Toronto, who was associated with Dr Banting in the research on insulin, spoke at the invitation of the President. He said that it was very interesting to learn that the problems confronting the clinicians in England with regard to insulin were very much the same as those which confronted the clinicians in Canada. Cases which came regularly to the out-patient department seemed to get along comfortably, the trouble arose in cases which were seen only at irregular intervals. To overcome this difficulty the General Hospital at Toronto had developed a special branch of its social service department for keeping in closer touch with these patients. As Dr Graham had said, the occurrence of infection in these diabetic cases under treatment was the great bugbear of the clinician, and there did not seem to be any particular way of overcoming it save by early recognition of the infection and increasing the dose of insulin or adjusting the dietetic treatment. In the cases in Toronto where there had been no infectious progress had been very smooth. It might be of interest to state that the first patient who ever received insulin—a lad named Thompson, on January 11th, 1922—was now a very healthy young man, and to all appearance perfectly normal. The experiences described by Dr Lawrence were interesting, and in line with what one would expect from the increasing tolerance of diabetics after exercise, as noticed even before the days of insulin.

Use of Insulin for Child Diabetics

Dr G A HARRISON spoke of difficulties in the use of insulin in the case of children. In children it was essential to give a sufficient number of calories to permit of growth, and the diets, therefore, were relatively large. On account of these high diets in children the difficulties of insulin treatment were perhaps greater than those encountered among adults. Some American writers appeared to have come to the conclusion that if the daily requirement of insulin was 10 units it was a safe working rule to give one injection only, but if it exceeded 10 units more than one injection should be given. This might serve as a rough and ready rule, but it should not be followed out to an extreme

In severe cases requiring large doses of insulin these writers favoured the giving of three or four injections, usually one before each of the principal meals, and another at midnight. In children this would be a very serious undertaking for those who had supervision of them. It had to be remembered that very often the moment of injection was one of terror for the child, also the skin became extremely hard with multiple injections. The speaker tried to work with a maximum of two injections in twenty-four hours. In very severe cases he had failed to get the blood sugar normal for the whole twenty-four hours, the patients tending usually to have a rise in blood sugar after the night's rest. Inter-current sepsis was apt to be very sudden and serious in children, and to cause a great deal of worry to the family doctor. The doctor heard, perhaps, that the child was not taking the prescribed diet, and, thinking of the dangers of hypoglycemia, he stopped the insulin entirely, but here he was in a difficult position unless he had access to frequent blood sugar estimations. One would assume that reduction of diet required a reduction in insulin, but the patient suffering from an acute illness might have a considerable carbohydrate store from which to draw. If the requirement of insulin had exceeded 10 units the insulin should never be omitted completely, even if the patient was taking no food at all. Dr Harrison suggested that milk be substituted for the prescribed diet, and that if the dose of insulin had been 10 units it should be reduced to 5, and if it had exceeded 10 units it should be reduced to two-thirds. In these acute cases he could not advise the complete omission of insulin.

Experiments on Blood Sugar in Animals

Dr P J CAMBRIDGE said that it appeared to have been taken for granted that all forms of diabetes were the same. His experience was that the condition met with in children was distinct in etiology and perhaps had a distinct origin. Some recent experimental work in which he had participated was of interest in this connexion. It had shown that a high blood sugar was of a Mendelian recessive character. If an animal with high blood sugar were mated with a normal blood-sugar animal the progeny would have normal blood sugar, but on breeding from these a proportion of high blood sugars and normal blood sugars in accordance with the Mendelian theory would be found. The reason why a high blood sugar was a Mendelian recessive was probably that the level of the blood sugar depended on a number of factors. He, with others, had proved by chemical experiments that insulin and adrenaline had opposite effects upon the activity of certain sugar ferments, whereas insulin and pituitrin had not opposite effects, but neutralized each other chemically. If a patient with a normal pituitary were given constantly excessive doses of insulin his pituitary gland would probably be exhausted, and a condition of diabetes insipidus in a mild form would be set up. Experience of elderly diabetics showed that the majority had a hyperactive thyroid. There was no direct antagonism, apparently, between the thyroid and insulin, but thyroid did activate adrenaline, and therefore when there was a hyperactive thyroid a force opposed in its activity to insulin was increased. If a patient with such a thyroid were given sufficient insulin to make him sugar-free, and then as a result of diet and careful treatment had his thyroid activity diminished, the insulin hitherto given without difficulty would be found to be an overdose.

PERUTERINE INSUFFLATION OF FALLOPIAN TUBES IN STERILITY

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, held on October 1st, the President, Mr T G STEVENS, in the chair, a paper was read by Dr I C RUBIN of New York on the diagnostic value and therapeutic application of peritoneal insufflation of the Fallopian tubes in cases of sterility.

Dr Rubin said that he had begun the search for a non-operative method of determining tubal patency in 1914 by animal experiments. Collargol was injected through the uterus into the Fallopian tubes, and radiographs were

prepared. The use of gas instead of opaque solutions commenced in November, 1919, at the Mount Sinai Hospital, New York. Oxygen was allowed to pass into the peritoneal cavity of a patient who came to the hospital for the relief of sterility. The abdomen was seen to swell, the patient complained of distension and epigastric pain, in the upright position pain was also felt in the shoulders and in the diaphragmatic region, and general pneumoperitoneum was shown by x-ray plates. The quantity of gas introduced at this first experiment was estimated to be about two litres, and it was realized that less gas must be used, some manometric control instituted, and some method devised for measuring the volume of gas. With the aid of the siphon volumeter and a mercury spring-type manometer, a small degree of pneumoperitoneum was found to be easily demonstrable by fluoroscopy. Carbon dioxide gas was substituted for oxygen, since it was very rapidly absorbed from the peritoneal cavity, and, when used in amounts of 150 ccm. or less, the phenic irritation and shoulder pains were only momentary. The test thus became simple, it required only one or two minutes to perform, and the patient could leave after five or ten minutes in perfect comfort. After describing the apparatus and technique employed, Dr. Rubin proceeded to explain the interpretation of the results. When the Fallopian tubes were normal the mercury rose to 40, 60, 80, or even 100 mm., and dropped 10 to 40 points, with frequent fluctuations, until the cannula was withdrawn. Usually there was slight pain referable to the uterus, lateral pain was seldom felt. The fluctuations in pressure were due to tubal peristalsis. When, however, one Fallopian tube was closed or stenosed and the other was normal, the patient complained of pain on the side of the obstruction, with both tubes stenosed or closed the pain was bilateral. This pain, due to distension of the tubes on the proximal side of the point of obstruction, occurred whenever there was obstruction at any point beyond the isthmus. When the manometer rose to 200 mm. of mercury, and uterine colic, or pain referable to the suprapubic area, was felt, but no pain on either side, the closure was situated at the intramural portion of the tubes, or very near the isthmus of each side. The high pressure required to overcome the organic obstruction or stenosis was distinguishable from that due to tubal spasm. As contraindications and dangers, Dr. Rubin cited pelvic or genital suppuration, pelvic tenderness, inflammatory masses, and pyrexia. At the time of insufflation the patient must not be menstruating, nor bleeding from other causes, nor should the test be performed in the presence of serious cardiac, renal, pulmonary, or great general metabolic disturbance. There was practically no danger in the method when properly performed, and untoward effects only followed in the infrequent instance of chronic tubal suppuration where the fibrinated end was still open, the pus was, however, usually innocuous.

Passing to the therapeutic application of tubal insufflation, Dr. Rubin stated that though up to the present the collected data were inadequate, yet in one series of 1,000 consecutive insufflations 95 cases of pregnancy had been voluntarily reported, and in another series of 763 patients 52 pregnancies had followed. He believed that the test could be considered of definite value when a woman, sterile for a previous period of five years or more, became pregnant during the month after peruterine insufflation. He considered that this procedure aided the sterile woman by establishing patency of the genital tract from the external os to the abdominal opening of the Fallopian tubes, by the expulsion of a mucous plug, not visible at the external os, but occupying the deeper portion of the cervical canal, by straightening out tortuous tubes, dislodging a mucous impaction from a narrow to a wider portion of the tube, and by separating adhesions at the fibrinated ends, and by the mental impression on the patient. He concluded with a list of indications for peruterine insufflation. This included primary sterility, primary sterility in which the patient had passed through a gonorrhoeal pelvic infection, sterility following a pelvic exudate or abscess complicating a puerperium or abortion, primary sterility after peritonitis of appendicular origin, one-child sterility without definite history of pelvic infection after the removal of one whole tube and part of another for hydrosalpinx or pyosalpinx,

and as a therapeutic measure to eliminate the tubal factor in sterility.

Dr. T. W. EDEN said he had used the apparatus introduced into this country by Currier of Montreal, solely as a method of diagnosis, and he did not know that therapeutic effects were claimed for it until listening to Dr. Rubin's paper. He thought that an extensive use of the apparatus by a number of different observers should be made before accepting the view that the passage of gas through the uterus and tubes could clear away organic obstructions which were the cause of sterility. He agreed that a complete block could be registered by this instrument even when the tubes were patent. He had recently had two such patients, both having been operated upon immediately after the test was made. In one the block was apparently due to kinking of the tube from retroversion, in the other the only morbid condition found was a small interstitial fibroid in the fundus which might have so distorted the uterine cavity as to prevent the gas from entering the tubes even under considerable pressure.

Mr. S. FOSSDIKE said that inflation of the uterus and tubes had become a routine procedure in the diagnosis of female sterility, and the question was which was the best technique. Dr. Rubin, with some justification, considered his apparatus the best, condemning the syringe and bulb methods on account of possible fallacies due to a faulty bulb or leaking valve. Mr. Fossdike had been using the bulb method for some time, and found it sufficiently reliable to justify him in continuing with it, considering its simplicity. In about 5 per cent. of cases air failed to pass through the tubes where it was found that they were patent on subsequent examination with hysterosalpinx. The greatest drawback to Dr. Rubin's method was that he relied upon the x-ray diagnosis of pneumoperitoneum. In Mr. Fossdike's method the patient was in the Trendelenburg position, and the vagina was filled with saline solution to indicate any escape of air. The pubic area formed the dome of the abdomen, and the diagnosis was established by auscultation over the abdominal aorta where the air bubbles could be heard escaping, and by percussion over the suprapubic area where an increasing note of tympanites proved the pneumoperitoneum. Inflation alone was insufficient, and it was necessary to carry the investigation further by means of opaque substances, if inflation was negative nothing was known as to the site of obstruction, which knowledge was essential for the ultimate decision whether an abdominal operation was justifiable. Dr. Rubin discredited the investigation by opaque substances on the ground that he was able to decide the seat of obstruction by the area in which the patient complained of pain—that is, centrally or laterally, the speaker hoped that Dr. Rubin would correct this impression by trying a series of cases with opaque bodies.

Mr. VICTOR BOWLEY said that Dr. Rubin's work constituted one of the biggest advances in gynaecology of recent years. One of the most important things that inflation had taught was the futility of a large proportion of the salpingostomies performed before Rubin's discovery. He was perfectly certain in his own practice that in nine out of ten cases the tubes had remained blocked at the uterine end in spite of the new abdominal ostium. A new set of statistics would have to be prepared dealing with the cases operated on since inflation was practised as part of the operation. He doubted very much whether inflation in the consulting room would ever come into vogue in this country. The majority of women here would not submit to any operative procedure without an anaesthetic, and, moreover, it increased the danger, as Dr. Rubin had pointed out, of the procedure being carried out by relatively unskilled practitioners in unfavourable surroundings.

Mr. ALEC BOURNE had been using the form of apparatus demonstrated to the Section of Obstetrics and Gynaecology of the British Medical Association at Portsmouth in 1923 by Dr. Gilman Currier, of New York, and had been very pleased with the results obtained. He thought that in routine practice the use of x-rays was a serious disadvantage, and if proof of successful insufflation could be obtained by simpler means than radiography the apparatus would have a much wider scope.

Reviews.

INTERNAL SECRETIONS

Drs DODD and DICKENS, in their book *The Chemical and Physiological Properties of the Internal Secretions*,¹ have collected a large amount of very interesting information. They explain in their preface that the book makes no claim to originality, but was published largely in the hope of sparing other workers the dreary task of rummaging the endless literature dealing with the internal secretions. Fortunately, in addition to collecting the literature they have also edited it, and have thus spared their readers from being asked to read accounts of masses of wholly unreliable work, with which the literature of the subject unfortunately abounds. The book is concerned chiefly with the chemistry of the internal secretions, which is one of the most complex and difficult subjects in biochemistry.

The first chapter deals with the chemistry of insulin, and gives a very clear account of the remarkably rapid development in the method of insulin extraction which has occurred since 1922. The rapidity of the advance is indicated by the fact that in that year the yield was only about 10 rabbit units per kilo of pancreas, whereas to-day yields of over 2,000 units per kilo are obtained. Moreover, by the original methods the end-product only had an activity of one rabbit unit per 20 mg., whereas products 200 times as active are now obtained. The account of the way in which one advance has succeeded another during this short period is very interesting. In the case of the thyroid and the adrenals biochemistry has advanced a stage further, for the formulae of the active principles is known, and in the chapters dealing with these substances a full account is given of the complex methods by which thyroxine and adrenaline have been isolated and their formulae determined. The chapter on pituitary extract is not quite so satisfactory, but in this case nothing has been ascertained concerning the chemical nature of the active principle, and we do not even know whether it is one substance or four, consequently it is not easy to give an account of its chemical properties. A short but very interesting chapter is devoted to the ovarian secretion. Allen and Dorcy have evolved a method for estimating quantitatively the activity of ovarian extracts by observing their effect on the oestrous cycle of rats. This method promises to establish knowledge of the internal secretion of the ovary on an accurate basis. The authors point out that this will now prove of the greatest importance both to clinicians and physiologists.

The fact that it is now possible to collect sufficient reliable data to write a book on the chemistry of the internal secretions is pleasing evidence that knowledge of this subject is rapidly advancing. The authors have had the advantage of dealing with an aspect of internal secretion which is wholly dependent on experimental evidence, most of it quantitative, hence they and their readers have been spared the vague guesses and unsupported hypotheses which bulk so largely in much of the literature on this subject. The book will be of great value to all who are interested in the physiology of internal secretions.

ALCOHOL IN MEDICAL PRACTICE

Dr C C WILKES, in his book *Alcohol in Medical Practice*,² makes a strong attack on the use of alcohol in therapeutics, but as he is careful to give facts and authorities in support of all his conclusions his book is a great deal more interesting and instructive than is often the case with works of propaganda.

He has collected statistics from nearly all the hospitals in the British Empire concerning their expenditure on alcohol in 1900 and 1923 respectively. These figures show that the consumption of alcohol in hospitals all over the world has decreased in a remarkable manner during the

last twenty-five years. The average consumption per patient per annum has sunk in the last twenty-three years from the equivalent of 6.8 oz of brandy to 1.3 oz. Owing to the rise in the price of alcoholic drinks, however, the expenditure per occupied bed has only sunk from 13s in 1900 to 9s in 1923. The expenditure of the various hospitals is set out in detail and some remarkable variations are to be noted. For example, the expenditure on wine and spirits in the London teaching hospitals varies from 5s 2d to 32s 7d per occupied bed. The author very reasonably adduces this variation as evidence that the use of alcohol in disease is determined more by custom or caprice than by any obvious therapeutic necessity.

He has no difficulty in demonstrating the complete falsity of the popular view that alcohol is a stimulant and in particular he shows that the pharmacological evidence is unanimous in proving that alcohol does not act as a circulatory stimulant. Furthermore, he has collected an imposing amount of clinical opinion against the use of alcohol in pneumonia and shock. In the chapter on alcohol as a food and gastric adjunct it is shown that it is a very expensive food of peculiarly limited value. The action of alcohol as a gastric adjunct is not denied, but the author urges social reasons against its prescription as an aid to digestion.

The final chapter of the book deals with the evolution of medical opinion regarding the action of alcohol, and it is particularly interesting to read the arguments used by Drs Todd and Chambers for and against alcohol in the early sixties. Dr Todd believed that alcohol augmented the generation of nervous power, increased the animal temperature, strengthened the action of the heart, reduced the frequency of the pulse, and that, by its action as a food, it shielded the tissues from the influence of oxygen. Naturally he believed that it was difficult to give too much of a substance endowed with these remarkable properties. Dr Chambers, on the other hand, believed that alcohol lessened the power of the nervous system, and arrested and obstructed the vigour of vital action, and thus diminished vital metamorphosis. It is only when the reader is referred to controversies such as these that he realizes of how recent growth is the science of physiology. The author, however, has no difficulty in showing that the whole tendency of modern medicine has been to whittle down the therapeutic claims made for alcohol and steadily to diminish its use. The book concludes with the words, "Thus we reach, under the converging influences of scientific and sociological evidence, the position of to-day in which we find all the world over an increasing disposition to entail in every direction the use of alcohol in the treatment of disease." As the author remarks, "To no other pharmaceutical or therapeutical question is it more difficult to bring a clear and unbiased mind than to that of the use of alcohol." He would probably not claim to be unbiased, but he may reasonably claim that he has been perfectly fair in marshalling the arguments against the use of alcohol in medicine, and he is to be congratulated on his industry in amassing the interesting statistics reproduced in this volume.

MYOPE CLASSES

Dr JAMES KERR has written a very instructive little book on the work of the London myope classes. Anything that Dr Kerr writes upon school medical work must command attention, for he was so intimately associated with that work both in Bradford and in London for many years during a period marked by a wave of reform in school methods and the beginnings of regular school medical inspection and of treatment. His book is entitled *School Vision and the Myopic Scholar*.³ It is an account of the general processes of vision particularly as affecting children with short sight. There is a brief history of the origin of the myope class, which dates from a paper read by Mr Bishop Huxman at the International School Hygiene Congress in 1907, and

as a fortunate result fourteen myopes and six others with very defective vision were gathered into a class which was opened at Boundar Lane in January, 1908. From this the whole system has been developed by watching every opportunity. This was a class for helping lame dogs over stiles to use Harman's phrase, but as most of its attendants were short sighted and it was out of

³ *School Vision and the Myopic Scholar*. (Book for Teachers and School Workers.) By James Kerr M.A. M.D. D.P.H. London: George Allen and Unwin, Ltd. 1925. (Cr. 8vo pp. 155, 28 figures 5s. net.)

¹ *The Chemical and Physiological Properties of the Internal Secretions*. By F. C. Dodd, Ph.D. B.Sc. M.B. B.S. and F. Dickens, M.A. Ph.D. Oxford Medical Publications. London: Humphrey Milford, Oxford University Press, 1925. (Demy 8vo pp. xiv + 214, 3 figures 8s. 6d. net.)
² *Alcohol in Medical Practice*. With a chapter on the Evolution of Medical Opinion. By C. C. Wilkes, M.R.C.S. L.R.C.P. London: H. K. Lewis and Co., Ltd. 1925. (Cr. 8vo pp. 177, 185 figures 3s. 6d. net.)

the agitation for special education for high myopes that it had come the name 'myope class' became established.

Dr Keil does not like the name, but concedes that it has become fixed. Since the book is intended for the use of tenebrists and school workers, he gives clear and simple accounts of the anatomy and physiology of the eye, of some of its most common defects, and particularly of myopia. The educational treatment of the defective children is then dealt with in detail. There is a glossary of medical terms. The book is well written and is calculated to be useful to those who have to tend and educate children with defective vision.

DISEASES OF CHILDREN

THE appearance in English of Professor L. FEER's book, *The Diagnosis of Children's Diseases*,⁴ is to be welcomed. The translation is from the third edition, and has been done by Dr C. A. SCHERER. The book is of a special kind, for it is not a textbook of disease in childhood, but a systematic description of the symptoms and physical signs of disease, with special reference to diagnosis. The reader will find little about etiology or pathology and almost nothing about treatment, so that the book must be studied along with some complete treatise. But symptoms (in the broad sense) are the manifestations of disease, and it is by observation of these phenomena of disturbance that a diagnosis is made. It is of great value to the student and practitioner that symptoms should be studied as a branch of knowledge and training, and the thanks of teachers and students alike are due to Dr Feer for making this interesting experiment in the presentation of his subject. The symptoms and signs of disease dealt with in the book are those revealed by the bedside examination of the child, and throughout the attempt is made to reach a diagnosis by these alone, and to resort to more technical and elaborate tests only for corroboration of the clinical diagnosis. After some introductory remarks about special difficulties and special methods in the clinical examination of infants and young children, the study of symptoms is begun in a systematic way. The facial expression, the form of the body as a whole, the parts of the body, such as the skin, hair and nails, hands and feet, eye, ear, nose, mouth, and so on, are successively dealt with, abnormalities and their significance in diagnosis are systematically described.

Although the book is thus one on the symptomatology of disease in children and on clinical methods of examination, it is more than a dictionary of symptoms. Under each system there is a short account of the commoner diseases—for example, of the diseases of the bronchi and lungs, of pulmonary tuberculosis, of congenital and acquired heart diseases, and of the nutritional disorders.

The illustrations are numerous and they are unusually good. It is seldom that the finer shades of facial expression are so well brought out. There is a special index of illustrations arranged according to diseases. The book is an interesting experiment, and ought to be useful to both the student and the practitioner, read in conjunction with an ordinary textbook. It gives the ripe experience and observations of a distinguished physician and teacher, and Dr Scherer has done good service in making it available to the medical profession in Great Britain and America.

In his book on the dystrophies of adolescence⁵ Professor V. HUTINEL discusses the subject in an appropriately general and philosophical way. Dystrophy is taken to be almost any disturbance of the normal life-process, that disturbance may be local or general, it may be atrophy or hypertrophy. Thus obesity and emaciation, gigantism and dwarfism, are alike regarded as dystrophies, further, dystrophy may have only a local manifestation, and genu valgum, scoliosis, with many other examples, are described as "dystrophies monosymptomatiques." In a preliminary chapter normal life in its periods of growth, maturity, and decline is described, and then a short account is given of the "dystrophies" of infancy and childhood, including rickets, the wasting diseases proper, status lymphaticus, and the uremias. The

ground is thus cleared and a correct mental focus adjusted for the main subject—the dystrophies of the period of adolescence, when the sexual functions come into play and the activities of human life become complete. The glands of internal secretion and the vegetative nervous system are described in relation to normal nutrition, and interesting clinical examples of their disturbance are given. A good deal of emphasis is also laid on congenital syphilis as a factor in cases of general malnutrition and disturbed health in adolescent life, and some striking cases are quoted. At the same time a warning is sounded against an exaggerated view of its importance—"il serait imprudent de le voir partout." The book is a philosophical essay on a very wide subject, although it does not neglect clinical applications. It is based on wide experience, and is written in a most graceful and attractive style.

SAVINGS

THE professional man who is a master of his own work recognizes that he is at sea in the field of another profession, yet there are occasions when it is imperative that he should be sufficiently instructed in some other work to allow him to wall wail. In no circumstance is this knowledge more necessary than in the investment of savings. It is not easy to save, but it is still less easy to secure those savings. The days of the stocking and iron box are gone. We seek to make our savings reproductive, it is good that they should be. The talent wrapped in a napkin is of little use to anyone, wisely invested it will earn other talents.

Mr HARGREAVES PARKINSON has written a most useful little book entitled *The A B C of Stocks and Shares*.⁶ It is a guide to the investor. He describes the working of the Stock Exchange, the relative spheres of the broker and jobber, modes of buying and selling, and settlements. The distinction between investors and speculators, and such terms as "bull," "bear," and "stag," are explained. The net of the bucket-shop dealer is spread in the sight of the reader. The values to the investor of debentures, preference and ordinary shares, and their relations to different types of companies, are given. Finally, the reader is told how to read a balance sheet, and what to look for as indicators of the stability of the company. The prudent investor will take the opinion of his broker, who should be a member of the Stock Exchange, but for all that he should have a nodding acquaintance with the data given in this book.

NOTES ON BOOKS

DR G. S. HAYNES'S small book of *Notes on Medical Case Taking and the Examination of Patients*⁷ is designed for the use of students at the very beginning of their clinical work in the patient departments. It begins, as the title indicates, with the interrogation of the patient, and the examination. Dr Haynes's description of the theory and practice of physical examination starts the reader on sound lines which he will, later on in his career, find continued in the larger works of other authors (such as Hutchinson and Ralby) that may be regarded as the standard authorities in common use. The book is well and clearly written, and may be recommended with confidence to those for whose use it is designed.

In compiling his *Textbook of Biology*⁸ Professor W. M. SMALLWOOD adopted an unusual plan. He begins with the frog, the first part of the book being intended to teach the fundamental principles of biology as illustrated by a complex animal. From the complex he passes to the simple and expounds the fundamental principles of biology as illustrated by unicellular organisms. With these types as a basis the author proceeds to the systematic study of various plants and animals, and, finally in the fourth section, leads the reader to theoretical interpretations of biology such as the theory of evolution and heredity. Instead, therefore, of beginning at the bottom of the evolutionary tree and expanding upwards Professor Smallwood works on the plan of

⁸ *A Textbook of Biology*. By William Martin Smallwood, Ph.D. Fifth edition. London: Baillière Tindall and Cox, 1925. (Roy. 8vo. pp. 747 + 393. 245 figures. 16s. net.)

beginning with the forms of life with which the student is most familiar and works out from this in both directions. It appears that this method of presentation has been appreciated by the students the author teaches, judging from his remarks in the preface to this edition.

Dr RICHARD H. HUNTER'S *Short History of Anatomy*, which is intended for medical students entering on their anatomical course, fulfils its purpose well. It gives a concise and readable account of the subject from the time of Hippocrates to the passing of the Anatomy Act in 1832. The student will not only learn from this book something about Herophilus, Galen, Sylvius, Vesalius, Fallopius, the Hunters, and the Monros, to mention only those who have given their name to some anatomical structure, but will also gain a clear idea of the difficulties with which the early anatomists had to contend. The work is to be warmly recommended to the student who wishes to take an intelligent interest in anatomy.

MOTOR CARS FOR MEDICAL MEN.

FINAL IMPRESSIONS OF THE MOTOR SHOW By H. MASSAC BUIST

THE curious policy of the Standard Company in respect of the manner in which its new 12/24-h.p. car was placed on the stand on press view-day, and announced to the press later, explains why it has been missed over. The procedure is not calculated to assist in securing it that measure of attention it might otherwise have received. The announcement on behalf of the company states that this car is supplementary to its 11 h.p. and its 14 h.p. types. It is a £12 tax chassis with an overhead valve four-cylinder 1,943 c.c.m., 12/24-h.p. engine, having forced lubrication and magneto ignition, a right-hand controlled three-speed gearbox, a dual-plate clutch, gartered half-elliptic springs back and front, supplemented by shock absorbers, reinforced balloon tyres, and four-wheel brakes. It is catalogued at £215, or with five-seat body at £275, and as a saloon at £335, both with four wide doors. The open car is of the all-weather hooded type with separate and adjustable front seats, the windscreen being of the two-pronged type. When out of use the six detachable side-screens are stored behind the rear upholstery.

Standard light car bodies have always been notable for their roominess. This 4 ft 8 in. track and 9 ft 4 in. wheelbase chassis provides room for spacious coachwork without excessive overhang required.

Low of the seven lights on the saloon can be lowered into, or raised out of, the hollow doors by means of automatic regulators. The back light extends almost to the full width of the car panel. Companions are fitted at each side of the rear seat, being sunk flush into the body framing. The equipment is comprehensive, and the buyer has the choice of three colour schemes.

The Ford Fiat Cablegim

But the sensation of motor show week has been furnished by the cablegim from America to the effect that Ford and Fiat had formed a world-wide combine. This is the first exhibition at which the 7-h.p. overhead valve four-cylinder engine half-elliptic spring four-wheel braked Fiat chassis has been shown in the form selected for standardization after over three years of experiment by the pioneer firm of the Italian industry, which has the largest output of cars in Europe and the greatest international reputation in long-distance road racing during the last twenty years. That chassis shows in every line advanced standard car construction of the most efficient, durable, refined, and economical sort such as could have been arrived at by no other means. It is one of the two most completely self-explanatory examples that this exhibition affords of what experiment means to the advance of automobile construction for world-wide daily service to the public.

I cannot get an official denial of the statement contained in the above mentioned cablegim—I deliberately phrase the matter so—and it is within my knowledge that for a long time past the leaders of the American industry (which knows nothing about the small car for which there is, never

theless, a world-wide demand) have been experimenting with the Morris as evolved and built in this country, with the Citroën as evolved and built in France, and with others. With their world-wide ramifications, the major American organizations consider they have the middle size and large car trade in every country in their hands. But they recognize that the conditions in their own country have not been ripe for the introduction of the small car, that there nevertheless exists a world-wide demand for such a product outside the borders of the United States, that the problems of successful design require much greater knowledge and experience than their automobile engineers possess, and that there is not a moment to be lost if the well-impoised countries—Britain, France, and Italy—are not to enjoy practically the monopoly of this branch of motor car building. Nor will the American Government look down on the contrary, it is urging transatlantic manufacturers to go ahead with small car building without waiting, an appreciable demand within the borders of the United States. To this end it has shown them how an export market could be found for an output of 40,000 small cars of any one make in twelve months, considering activities all over the world being directed to getting statistics of local conditions which, in the aggregate, total that figure.

What American Motors Want to Know

Operating solely on its own initiative, the Fiat Company could entirely recast the small car proposition the world over by the standardization of this new 7 h.p. chassis because it is theoretically a correct automobile engineering job from end to end. It is a design which lends itself to stampings and pressings, and therefore to reproduction by hundreds of thousands or millions of examples. Despite its simplicity, it is "stiff" in a sense new to small car practice even as it is, of light weight, simple and road-worthy, as the frame, half-elliptic suspension, low centre of gravity, and four-wheel braking details attest. I do not think I shall prove a false guide in intimating that it eclipses the remarkable 10/15 h.p. Fiat, itself world famous for efficiency in a quite different class. The new small car can take any type of body suitable to the medical man's needs.

Whether the individual has a practical or merely an academic interest in its advent, this chassis should be looked at because it can explain much to those unversed in technical matters concerning the vital problem of what it is essential to incorporate in a sound engineering job and what can be left out with advantage. That I am not suggesting a waste of time will be obvious from the fact that the American automobile engineers are unable to think in the simple terms that experiment has enabled these Italians to employ.

How to Learn to Judge a Car

I have to record two other last impressions of new design as introduced at this show, which are calculated to be of service to the medical man. It is that he should make careful inspection of the new £18 tax nominal 17/75-h.p. overhead valve six-cylinder engine £650 Daimler chassis with right hand controlled gearbox providing four speeds forward, single plate clutch, spiral bevel back axle drive, and internal expanding brakes on all four wheels. This machine presents in middle size car practice a blend of Anglo-Franco-Italian automobile engineering design in the light of the latest experiences. Only the expert looking at it can realize fully how clever has been the solution of the problems involved. Instead of conveying the idea that it is probably the second most difficult chassis to design of any at the show, it will strike the average motorist that it must have been the easiest because the way everything is done looks so obvious.

The other chassis should be studied in part only at this juncture for the purpose under consideration. The single sleeve valve six-cylinder engine 11-h.p. chassis indicates what will be done universally somewhat in this style one day to rid us of the nuisance of spring shackles and shackled lubrication.

Whoever studies these examples will furnish himself with means to understand the metrics of motor car design more clearly, in other words, after giving himself such a lesson he will see more in any chassis he looks at.

British Medical Journal.

SATURDAY, OCTOBER 17TH, 1925

OSTEOPATHY AND CHIROPRACTIC

IN an article on osteopathy and chiropractic published in our issue of May 31st, 1924 (p. 963), we endeavoured to outline the main features of those cults, and hinted that a surplus of this American product was likely to be dumped into this country in the near future. It is impossible to estimate the number of arrivals since that date, but the settlement has so far advanced as to induce osteopaths to demand formal recognition and a legal status, a matter to which we made reference in a leading article on April 11th last (p. 706). Their cause has also been espoused by a small group of members of Parliament, and the Minister of Health (Mr. Neville Chamberlain) has received a deputation in support of it.

The subject is one that bears, not only on the safety of the public, but also on the interests of medical practitioners, who will, therefore, be well advised to make themselves acquainted with its details. For this reason we welcome the forcible pronouncement of Sir Holburt Waring in his presidential address to the Medical Society of London published in our present issue at page 679. He has done good service to the profession in making plain the real nature of these cults and insisting on the necessity of taking steps to counteract their influence. As several speakers seemed to recognize in the discussion (reported at page 701) which followed the address, the problem of finding measures that will prove effective is not easy of solution, and is not likely to be solved without a thorough understanding of the conditions to be dealt with.

It will be noticed that there are two distinct cults, although they both rest on the same fundamental tenet—that the displacement of anatomical structures from their normal positions is the sole cause of disease. The practical distinction between the cults is that osteopathy claims to be progressive, while chiropractic is stationary. The whole pathology of the chiropractor is embraced in one fundamental tenet. He needs no knowledge of disease, he merely needs to know in what part of the body the disease, whatever its nature, exists, his tenet assures him that the cause lies in the subluxation of a definite vertebra, and this he pretends to reduce. With this slender stock in trade of knowledge and technique he has proved a stupendous financial success. This was the original form of chiropractic, and it remains the same to day, the cult flourishes in America, and is probably more widespread in this country than some of us suspect. It is obviously pure nonsense, and therefore the appropriate measure to adopt in the first instance is to examine our existing laws and inquire whether they are adequate to their purpose and efficiently administered. It is the duty of the Legislature to leave no stone unturned to protect the less educated of our people from such persons and should the existing enactments appear to be insufficient, one of the recommendations of the Select Committee on Patent Medicines (1914) might perhaps afford a precedent. The Committee advised that the advertisement and sale of medicines pur-

porting to cure certain diseases, such as cancer, consumption, epilepsy, locomotor ataxia, and Bright's disease, should be prohibited. A similar index might be drawn up and chiropractors prohibited from treating diseases enumerated in it. The principle was embodied in a bill—the Proprietary Medicines Bill—introduced on behalf of the Ministry of Health into the House of Lords in 1920 by Viscount Astor, then Parliamentary Secretary to the Ministry. The bill contained a list of diseases in a schedule. It passed through the Committee stage in the House of Lords, and there were promises that it should be introduced in the House of Commons in the following year, but the then state of parliamentary business rendered them impossible of fulfilment.

The conditions are somewhat different as regards osteopathy. Doubtless a large number of osteopaths differ very little from the chiropractors above described, they may have a smattering of medical science, which not improbably renders them the more dangerous. But many have a considerable knowledge of modern medical science while retaining, or professing to retain, their original dogma. Thus we find it stated in the Supreme Court of Washington in 1917 that "a perusal of the successive catalogues of the schools of osteopathy will show that their teachings are gradually being expanded, and that the more modern of them now teach in some degree much that is taught in the older schools of medicine." Some osteopaths have even taken the regular medical degree. It is evident that we are here dealing with a different type from that of the chiropractor. Probably, however, in the majority of cases, the education of osteopaths is totally inadequate. Sir Holburt Waring points out that a student of an osteopathic or chiropractic school or college may attend and complete the whole of his course in eighteen months, laboratory instruction in the modern reception of the term does not seem to exist, and in most of the schools diagnosis or disease is not considered necessary, and ethical teaching is practised in an ordinary medical education is not given. We feel sure that the medical profession at large will endorse the opinion expressed by Sir Holburt Waring that "instead of the Legislature making possible the licensing of osteopaths in a very limited form of practice, the Medical Acts ought to be so strengthened that it would not be possible for the community to be treated by them or any other unqualified emulans or quacks", and that everyone who is licensed to practise as a medical practitioner in any form should be placed under the same requirements of knowledge and experience."

There is one further point deserving the consideration of the profession. Osteopaths, even without a licence, are engaged in practice, and, as we have already mentioned, some few have medical degrees. We have in Sir Holburt Waring's address the picture of the licensed and qualified osteopath as he is known in his native land. Whether he believes in his doctrine is a matter for his own conscience, but there can be no doubt that the retention of the name pains. It would be interesting to describe the numerous troubles that the medical profession in America has suffered from osteopathy did space permit, but one detail may be mentioned, since it is pertinent to the point we are dealing with. In some of the States medical men have publicly expressed the opinion that unless the tide of osteopathy and chiropractic is in some way stemmed they will themselves be under the necessity of resorting to wholesale advertisement if they are to hold their own! The name draws even in

this country, and that without the licence and qualification, nor is this by any means confined to the uneducated. The reason why this should be so is doubtless capable of analysis, we merely draw attention to the fact in order to suggest that medical men should take measures to inform their patients of the absurdities of these and other cults. A small volume, entitled *The Medical Follies*,¹ has recently been published by Dr Morris Fishbein, the editor of the *Journal of the American Medical Association*, it is written in an admirable style, and contains most entertaining and racy descriptions of celebrated founders of quack systems. If medical men would place a copy of this volume on their waiting room tables we think it would serve a useful purpose in disseminating a knowledge of the true inwardness of osteopathy, chiropractic, and other such pseudo scientific systems.

FOREIGN BODIES IN THE AIR PASSAGES

We publish this week (p. 686) the paper by Professor Chevalier Jackson of Philadelphia on overlooked foreign bodies in the air and food passages, with which he introduced the discussion on this subject in the Section of Laryngology, Otology, and Rhinology at the Annual Meeting of the British Medical Association at Bath, he afterwards gave a demonstration of the mechanical problems met with in the bronchoscopic and oesophagoscopic extraction of foreign bodies.

It is hardly an exaggeration to say that no greater development has taken place during the past quarter of a century in medicine and surgery than that of peroral bronchoscopy. Just as the laryngoscope in the past brought the larynx into view, so endoscopy has revealed the entire length of the oesophagus and the cavity of the stomach, and it has also exposed all the ramifications of the bronchial tree to direct vision. The rapidity of progress in this special branch during recent years is shown by the fact that it is only thirty years (1895) since Kirstein, following the work of earlier pioneers in the development of oesophagoscopy, first showed to laryngologists the possibilities of peroral endoscopy by introducing his direct method of examining the larynx—a method which broke entirely fresh ground, and was quickly followed by tracheoscopy and bronchoscopy.

Kilhan, greatly impressed with Kirstein's work, immediately began to devote his whole time to the study of endoscopy, with the result that, two years later, he was able to demonstrate the practicability of bronchoscopy, and to show that the air passages could be explored far beyond the bifurcation of the trachea. His early demonstrations created a profound impression, and laryngologists of every nation commenced vigorously to study this new branch. By introducing bronchoscopy Kilhan created a method by which a great saving of life has been accomplished, as shown by a reduction in the death rate from laryngoscopic cases of 30 per cent to between 5.3 and 1.7 per cent at the present day in the hands of the skilled endoscopist. By bringing to perfection instruments and technique he also made it easier for others to follow and carry on his work. Among those who followed in the footsteps of this great teacher, the father of bronchoscopy, no name stands out with more brilliancy and honour than that of Chevalier Jackson, who may well be termed the doyen of

endoscopists. The great Bronchoscopic Clinic which he initiated and has built up by his indefatigable energy stands as a landmark of his genius and of the work he has accomplished. This was recognized in 1920, when the University of Pennsylvania—the oldest university in the United States—established the first chair for the teaching of bronchoscopy and oesophagoscopy, and Chevalier Jackson, in whose honour the chair was founded, was made professor.

Nor were British laryngologists lacking in initiative or skill in developing this new branch of their specialty, for they early recognized the practical importance of Kilhan's work and quickly adopted his methods. Waggett, and D. R. Paterson (of Cardiff), in 1903 and 1904, were the first in this country to take up the study of Kilhan's work, Paterson contributing a paper to this JOURNAL in 1906 on "The direct examination of the oesophagus and upper air passages," while a paper by Waggett on "Direct laryngoscopy, bronchoscopy, and oesophagoscopy" followed in 1908.¹ Since that date many comprehensive articles have been published, and many cases of successful removal of foreign bodies have been recorded in our columns. During recent years endoscopic technique has been greatly improved and simplified, and the direct examination of the bronchi and oesophagus has become in this country part of the everyday life of the laryngologist, with the result that the removal of foreign bodies is now only recorded when some special feature or difficulty deserves recognition.

Endoscopy is not confined to the few. Each and every laryngologist has become his own endoscopist. Every young laryngologist considers the subject a part of his specialty, and trains himself to be capable of dealing with any case of foreign body which may come under his care. That this is so is confirmed by a summary of such cases compiled and published by Irwin Moore, which shows that 174 cases of foreign bodies successfully removed from the air and food passages, and reported to the Section of Laryngology of the Royal Society of Medicine between 1908 and the present date, were dealt with by thirty-six separate laryngologists, without special trained assistants or trained team work beyond the co-operation of a radiologist. These cases do not by any means represent the total number of foreign bodies removed in this country.

Chevalier Jackson's paper on overlooked foreign bodies, published in this issue, is of the greatest clinical and practical importance, in view of the fact that as many as 1,485 cases of foreign body have passed through his hands during the past twenty years, and that the data for his paper have been carefully compiled by him with the assistance of a skilled and devoted group of associates—Dr Ellen Patterson, Dr Gabriel Tucker, Dr Louis Cleif, and Dr Willis Manges—and the valuable help of Dr Thomas McCrue, Professor of Medicine in the Jefferson Medical College, Philadelphia, who, it will be remembered, delivered the Lumen Lecture before the Royal College of Physicians in 1924 on "The clinical features of foreign bodies in the trachea and bronchi." Amongst these 1,485 cases there were over 200 in which foreign bodies had been overlooked for periods varying from a month to thirty-six years, owing as Professor Jackson points out, to insufficient consideration being given—from a diagnostic standpoint—to the possibility of the presence of a foreign body. This is a large percentage in view of the fact that 98 per

¹ *The Medical Follies*. By Morris Fishbein. M.D. New York. Boni and Liveright. 1925. (Cr. 8vo. 1p. 223. 2 dollars.)

cent of foreign bodies in the bronchi and lung tissue, localized by present day methods, can be successfully removed by the skilled endoscopist with the help of *personal endoscopy*.

From a careful analysis of all the cases which have come to his clinic Chevalier Jackson enumerates the pitfalls which may lead to the overlooking of the foreign body, and cites illustrative cases. He is of opinion that one of the chief causes of failure is that a foreign body does not occur to the physician as a diagnostic possibility even in cases in which clear positive evidence is present, he attributes this failure to faulty medical teaching and training, and to the fact that a foreign body is rarely included in the list of diagnostic possibilities that ought to be excluded in every case of pulmonary disease. He lays it down as a general rule that the possibility of a foreign body must always be remembered in every ailing or sick child. The overlooking of foreign bodies may also be caused by failure to attach sufficient importance to the initial symptoms of choking and gagging, which are rarely absent when a foreign body reaches the air or food passages. Again, he lays down the rule that every case in which there is the slightest intimation of a foreign body, or of the patient having had an attack of choking, gagging, strangling, or coughing, should be looked upon as *prima facie* an example of foreign body. He maintains, in short, that a foreign body should be regarded as present until the contrary is proved by every means at command. The physician may be deceived by the absence of any history, especially in children, or he may not inquire with sufficient care as to an attack of choking or gagging.

The outstanding factor, however, in the overlooking of foreign bodies in the broncho-tracheal tree which deceives the physician is the "symptomless interval," often of prolonged duration, between the initial symptoms of choking and gagging and the later pulmonary symptoms. It is also to be remembered that in any given case more than one foreign body may be present, and that though one has been removed another or several others may remain. This mistake may be guarded against by the rigid enforcement of the rule always to have an *airway* examination made, not only before but after removal of any foreign body. It is possible that a foreign body may be coughed up, but this rarely happens, and waiting may be dangerous. Cases under Jackson's observation showed that only 3 per cent of foreign bodies known to have reached the bronchi were coughed up. The intimate association and co-operation of the physician, the radiologist, and the laryngologist in dealing with foreign bodies is consequently one of the most important factors in successful diagnosis and removal. A negative radiological report should not be taken as excluding the presence of a foreign body, but should always be followed, if there is any doubt, by endoscopic examination.

Cases of foreign body in the air passages may simulate in their physical signs and symptoms such common diseases as asthma, bronchitis, bronchio-pneumonia, empyema, abscess, bronchiolism, and tuberculosis. Chevalier Jackson maintains that until every medical practitioner is taught to consider it necessary to exclude the possibility of a foreign body in every case of acute or chronic pulmonary disease foreign bodies in the lungs will continue to be overlooked. Such conclusions and advice coming from a distinguished and experienced specialist should be taken to heart by every medical practitioner.

JAMES NIVEN

SIR GEORGE NEWMAN has sent us the following. I regret that, owing to my absence in Geneva on official business, I was unable to respond to your invitation to write a few lines on the loss which the medical profession has sustained by the death of Dr James Niven. At the Ministry of Health we all had a profound appreciation of this remarkable man, who was one of the deepest and most original thinkers that the public health service ever had. Again and again those who believed that they had broken fresh ground found the problems stated and their solution proclaimed in Niven's writings of years before. But he was always glad to help in subjecting even his own conclusions to the fire of criticism, and so long as the truth appeared to be more nearly revealed he seemed as enthusiastic in discovering flaws as in vindicating any theories of his own. His writings were not a reflection of the fashionable views of the moment, they were the result of original thought and prolonged personal observation. Indeed, they are to medical workers a legacy of immense value. His annual reports were studied by his colleagues in the public health service as classical statements which seemed to belong to the grand period of the middle nineteenth century. Much less was known of his writings than deserved to be known, as a great deal of his best work was only recorded in the annals of the Manchester City Council. They were, in his active period, extremely numerous, varied, penetrative, and suggestive, and his reputation amongst medical officers of health was such as no other man of his generation enjoyed. Niven's outstanding characteristic was his amazing vividness for work. He took to work as his pleasure, vocation, and duty. Not only did he labour for long hours and consume much midnight oil, but he worked with a fury of concentration that would soon have worn him out if he had not possessed an iron constitution. He never expressed an opinion on a subject until he had mastered it in detail, and any report presented to him which lacked the thoroughness he loved would lead to an interview in which the reporting officer was likely to be subjected to a ruthless cross-examination. Labour-saving devices did not appeal to him. He seldom dictated, but wrote out his correspondence and reports in his large, firm, characteristic calligraphy. Niven was not quick to comprehend a new idea. It would be received with something in the nature of a blank stare, which gradually changed into an expression of tentative welcome or rejection. In some matters, however, he had an intuitive quickness of apprehension. His judgement of a man was soon formed. But he had an open mind, and was always ready to consider any proposal, no matter how wild it may have appeared at first sight, or how much opposed to his own views. His habits of work were neither methodical nor conventional. He would carry important letters in his pocket, and discover them by accident inconveniently late for reply. Yet the working of his mind was a model of method. It worked like a first-class, well oiled, logical machine guided by a keen, critical judgement that rarely misled him. The expression of his considered opinion created the feeling that there was nothing more to be said. He was not a diplomat. He lacked the art of managing men to gain his object. His naive sincerity and his concealed but fiery sympathy with the suffering and the weak seemed an uncertain equipment for negotiations in municipal and professional affairs. But he met the cutest diplomatists apparently without being aware of their designs, and after a little hesitation calmly led the way to his appointed goal. His ideas triumphed by reason of their intrinsic merit, backed by his transparent sincerity. He was not a "popular" officer, but he was profoundly respected for his public spirit and his selflessness of aim. He scorned advertisement and the petty arts by which some men seem to advance in public

life. At our table round he was Sir Bois, grave and solid and thoughtful, but his smile when it came was a sunny one. Niven had reserves of manner which not infrequently warmed into asperity. Many who met him thought he was cold, but he was actually extraordinarily warm-hearted and kindly. In his intimate he had the tenderness of a woman and an unexpected and ample capacity for affection. Perhaps his most striking personal characteristic was the power he had of awakening in almost passionate affection in those who worked intimately with him. His staff became his disciples. When they met in later years he generally became the subject of their talk, and often stories of him were exchanged. The unique humour of these generally lay in some clash between Niven's great-hearted, absent-minded simplicity and the conventionality of some accidental circumstance. "I often think of you all," he wrote in one of his letters to an old pupil, "though only a dumb person." He found difficulty in making friendships, and much of what he wanted to say remained unsaid. Niven's department in Manchester was the training ground of many public health workers in whose memory he will live as the master from whom they learned their craft and as a dearly loved friend. They will remember those times when, at the close of some specially urgent and strenuous task, the "old man" over his pipe would pour forth a stream of reminiscence or humorous comment, expressed with a felicity of epithet and brilliant terseness of phrase that unfortunately seldom found its way into his public utterances. In such moments his rare and richly gifted spirit found congenial expression. His humour bubbled over, his good nature became a pervading influence. To those who were privileged to work with him the shock of his tragic passing has been keenly felt, but his memory remains as an inspiration and a precious possession, and his work endures, not as a memory only, but as a driving force and a guiding light of world-wide influence. Niven lives, and will live, in the results of his work, and such was the consummation which to his strong soul was that which was most "devoutly to be wished." He had no thought for self, and his kindness and generosity to those who were privileged to work with him is shown in his *Observations on the History of Public Health Effort in Manchester*, published at the time when he relinquished office. It might indeed be said of him—"His life was gentle, and the elements so mixed in him, that Nature might stand up and say to all the world, 'This was a man'."

OPPORTUNITY IN THE SERVICES FOR RESEARCH

LIEUT. GENERAL SIR WILLIAM LEISHMAN, K.C.B., F.R.S., Director General of the Army Medical Service, devoted his presidential address in the War Section of the Royal Society of Medicine on October 12th to the subject of research in the services. He explained that by research he meant, not only those experimental inquiries demanding expert knowledge and special equipment, but any work which had for its object to add to the existing knowledge of the causes, treatment, and prevention of disease. It was true that in view of diminished personnel the present time did not seem quite appropriate for suggesting to overworked officers that they should voluntarily add to their already heavy duties, but, after all, the services were only passing through a temporary phase of depression, and such a phrase, familiar enough to those who had seen long service, eventually passed away, and was succeeded by conditions better even than those which had preceded it. The facilities which the services presented for such research as he had defined were far greater than those enjoyed by most civil practitioners. Excellent material was available in the men over whom the medical officers had constant supervision, the past history of these men was well known and fully recorded, they were available for systematic or

periodical examination, and uniform standards of procedure could be employed. All this was, as a rule, out of the question in civil practice, save perhaps in connexion with schools and certain other institutions. The abundance and variety of the morbid conditions which came under observation in the services also called for remark. It was not infrequently said by people outside that officers in the service saw only the commoner ailments to which healthy young manhood was liable, and that the bulk of their experience was in the treatment of minor complaints and venereal disease. But this was not true even at the time when he joined the army, in 1887, and nowadays the volume and importance of medical and surgical work in the army—and he thought he could speak for the other services as well—compared favourably with that of all but the largest metropolitan or provincial hospitals. The equipment of the theatre and the laboratory in the services was maintained in a condition well abreast of modern requirements. Whatever tests were considered necessary as helpful to diagnosis or accessory to treatment were readily available, specialist and consultant services could be procured immediately, and altogether, in all but the most isolated stations at home or abroad, it was possible to carry out every method of investigation, and to observe and record the progress of cases by the most modern standards. Furthermore, all officers enjoyed the privilege nowadays of admirable post-graduate courses, just at the moment in their professional careers when they were likely to benefit by them most. Whether or not their professional predilections were sufficiently definite to lead them to seek for further special instruction in a particular branch, they were all given the chance of bringing themselves well up to date in their rapidly moving profession. A man in the services, therefore, was well equipped for making valuable observations along many lines of professional work, either by himself, or, what was often more desirable, with the readily available help of specialist colleagues. Thereby he made his professional life infinitely more interesting to himself, and there was always a chance that a particular investigation might end in bringing to light something of great importance. But Sir William Leishman warned intending investigators that two qualities were essential—absolute honesty and inexhaustible patience. The investigator needed some of the qualifications of the dour fly fisherman, for whom there was such hope in every cast as to carry him happily through a blank day and leave him with cheerful anticipations for the morrow. He went on to indicate, in admirably chosen words, the method of mental approach towards a piece of research. The young officer, he said, should begin by asking himself in what particular line of professional work he was most interested and would most desire to become expert, he should then think over the many branches of the chosen subject and select one or two of them for closer scrutiny. He should lay special stress on cases which in his own experience had puzzled him, in which he had felt unsatisfied as to explanations of etiology, or in which the treatment had proved in his hands unsuccessful, and, of course, he should acquaint himself with the literature of the subject. Presently he would find certain questions, challenges, and criticisms shaping themselves in his mind, and he should then ask himself how he could make and record his observations so as to give a clear-cut answer to his own questions. But he had also to remember that he must convince others as well as himself, and that those who heard or read his work would be quick to notice the absence of any relevant detail. With care, honesty, patience, and a cheerful philosophy he might confidently hope to reach some result worthy of communication to a society or journal. Better advice than this to the young investigator we have never heard. Sir William Leishman next touched on the value of collective research, in which several workers in different

places concentrate on the same investigation. It had been followed in the army with encouraging and substantial results, although the exigencies of the service had brought some promising lines of investigation to a premature halt. Such research not only accelerated progress, but multiplied the checks upon each observer, and the mere fact that workers at a distance from one another were engaged on the same problem and confronted the same difficulties stimulated intercommunication and broke down the isolated feeling of the worker who pursued a solitary line. In conclusion, the president spoke of the way in which the services, with their ideal conditions for observation and control, might help the civil side of the profession, which itself had been so generous in help to the services.

SIR WILLIAM HAMER

SIR WILLIAM HAMER, medical officer of health and school medical officer to the London County Council, who retires on December 31st next after serving the Council for a period of nearly thirty-four years, including fourteen years in his present position, will be entitled to a retiring allowance of £1121 a year, but in order to secure the benefit of his advice and experience after his retirement the Council, at its meeting on October 13th, decided to retain his services in a consultative capacity for a period of two years, and that he should receive a fee of 600 guineas a year for these services. At the same meeting a report was presented by Sir John Gilbert, chairman of the General Purposes Committee, placing on record the appreciation felt by the Council for the valuable services rendered by Sir William Hamer to the cause of public health in London during the period of his association with the Council. It was stated that one of the most important developments with which Sir William had been associated had been the growth and organization of the school medical service. When he took up his appointment in 1912 the scheme of medical inspection and treatment was in its infancy. Under his control it had become a far-reaching undertaking under which every year 300,000 children were medically inspected, 300,000 children seen by school dentists, over 1,000,000 vaccinations made by school nurses in connexion with the personal hygiene scheme, 1,500,000 attendances made by 230,000 children at hospitals and treatment centres, and over 100,000 attendances made at dispensing stations. The activities of the school medical service during this period had resulted in striking improvements in the health and physique of the children in the schools. On the general side of the public health work the most important development of Sir William Hamer's tenure of office had been the adoption of a comprehensive scheme for the treatment of tuberculosis, under which provision was now made for the institutional treatment of over 6,000 patients annually. Other new and important services which had been placed under his direction and control since 1912 included the scheme for the diagnosis and treatment of venereal diseases, the work of the former chemical department, the medical examination and supervision of defectives under the Mental Deficiency Act, the supervision of lying-in homes, and the supervision of nurse infants under the Children Act. His researches into the incidence of infectious diseases had made him one of the most distinguished authorities upon epidemiology. In particular his work upon typhoid fever and upon influenza and its associated group of diseases had furnished a series of brilliant reports to the Council, and had contributed materially both to establish clearer conceptions of the nature of these diseases and to open up new lines of preventive measures. There is reason to hope that, although the retirement of Sir William Hamer is on the ground of health this will not preclude him from undertaking the limited duties of the consultative post.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, ST ANDREWS

IN an address introductory to the winter session of the James Mackenzie Institute for Clinical Research, St Andrews, the honorary director (Dr Maitland Ramsay) gave illustrations from ophthalmology of the extreme value of symptoms in early diagnosis, and demonstrated how a knowledge of the mechanism of their production throws light upon the pathology of disease. While the act of sight is dependent on the integrity of (a) the dioptric apparatus, (b) the rods and cones, and (c) their nervous connexions, the functional unit which transforms light into nerve impulses consists of the rods and cones—an illustration of the essential importance of a study of receptors. Like all functional units, their efficiency is proportional to the state of their capillary blood supply, interference with which results in lowered efficiency. Disturbance of rods and cones leads to disturbance of light minimum, while diminution in activity of ganglion cells and nerve fibres is followed by alteration in the light difference. Congestion of the chorocapillaris, therefore, is followed by change in the light minimum and congestion of the capillaries supplied by the retinal artery by change in the light difference, these two symptoms being therefore of great diagnostic value. He added numerous illustrations to show the value of recognition of early symptoms in the diagnosis of serious diseases of the eye.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

THE new session of the London School of Hygiene and Tropical Medicine opened on October 5th. The class for the general course is full, and a number of applicants have been unable to gain admission. This is interesting in view of the fact that the course now occupies twenty weeks instead of eleven as formerly, and that the fee is thirty guineas in place of twenty. It will be remembered that the board of management adopted a scheme for the establishment of four research studentships, the holders of which, in addition to carrying out research in their respective subjects, are to act as demonstrators in the school. The posts were advertised, and from a number of applicants the following were selected by the Appointment Committee: Entomology, Dr Mary V. F. Beattie, helminthology, Dr Dorothy I. Milne, protozoology, Dr S. Anneke, tropical bacteriology and pathology, Dr W. K. Duncombe. Fourteen students have been enrolled for the special course in parasitology for the DPH. Thirteen of these are candidates for the examination. A few students have also been admitted for special courses. The new buildings of the school have not yet been begun, but we understand that the preparation of the plans is in an advanced stage.

I EM HETEP, THE EGYPTIAN DEITY OF MEDICINE.

THE eighty-fifth session of the Reading Pathological Society was inaugurated on October 8th by the customary oration, the orator on this occasion being Sir William Arbuthnot Lane, Bt, whose subject was "The causation of disease and the failure of civilization." A ceremony of unusual interest preceded the oration—the presentation by Sir Stewart Abram, physician to the Royal Berkshire Hospital and an ex-president of the society, of a president's badge or jewel as a souvenir of his term of office. Hitherto medicine has recognized as its patronal deity the somewhat legendary Aesculapius, who is supposed to have lived at the time of the siege of Troy, but of whom no biographical details are extant. The new badge of the Reading Pathological Society represents the far more venerable Egyptian deity of medicine, I-em-hetep or Imhotep, whose name signifies "he who cometh in peace." This famous Egyptian

lived about 2,900 years B.C., and was a learned, many-sided man, who filled, amongst other offices, that of vizier to a Pharaoh of the third dynasty named Zoser. Further, he was a noted architect, and built the earliest pyramid known to history, the Step Pyramid of Sakkarah, near Cairo. Above all, however, he was distinguished as a physician,

and so impressed his fellow countrymen with his skill in the *ars medendi* that he was eventually acknowledged and worshipped throughout Egypt as the deity of medicine. In his honour temples were erected in various parts of the country, and to them flocked patients from far and near. Many miraculous cures are reputed to have taken place at his shrines. The jewel presented by Sir Stewart Abiam consists of a pendant in hand chiselled gold and enamel, designed and made by Mr Omar Ramsden of London. The oval plaque of enamel represents I-em-hetep, the Egyptian god of medicine, the image of the god being

based on an exquisite early bronzo statuette in the Wellcome Historical Medical Museum. The god is shown in profile, seated on a golden "throne of knowledge," while his feet rest upon a footstool representing the solid earth, which is surrounded by a green band symbolizing the cultivated strip of land that is watered by the Nile. The river is of heraldic blue and white, flowing by in full tide; the background shows the blue sky of the East. The delectably wrought frame is surmounted by a double-headed and winged serpent, from which is suspended the Egyptian "ankh," the symbol of life. The border is made up of lotus buds springing from a lower space inscribed with the name "I-EM-HETEP." At the back is engraved the following inscription: "George Stewart Abiam commended me to be wrought for the Reading Pathological Society, in October of the year of our Lord MCMXXV." After a few words by the donor of this artistic badge, a cordial vote of thanks was proposed by the president of the society, Mr W. B. Nelson, who expressed the gratitude the society felt for this unique gift. In supporting the resolution Dr J. B. Hurry gave a sketch of the life of I-em-hetep, and pointed out how preferable it was for medicine to have as a patron deity a man of flesh and blood who had played a great part on the stage of history, rather than the semi-mythical Aesculapius, who is supposed to have lived about 1,700 years after I-em-hetep. To the Reading Pathological Society belongs the honour of having been the first in this country to recognize the claims of I-em-hetep to be regarded as the deity of medicine. "I-em-hetep," to quote the late Sir William Osler, "is the first figure of a physician to stand out clearly from the mists of antiquity."

AN UNUSUAL ANAESTHETIC FATALITY

An inquest was held by the West Ham coroner on October 8th on the body of a lad, aged 16, who died in most unusual circumstances at Queen Mary's Hospital, Stratford. On September 7th he had a cycling accident resulting in a fracture of the jaw, and an operation was performed on October 5th. Dr J. Keith Davidson, house surgeon at the hospital, said that in the course of the operation warm air had to be used in order to keep the patient's teeth dry. It

was applied with a dental syringe. Ether and oxygen was the anaesthetic employed. On the third application of the syringe an explosion occurred at the back of the boy's throat. Acute haemorrhage followed, and despite every attention the patient died within ten minutes, he had been under the anaesthetic for twenty-five minutes. Mr Percival P. Cole, surgeon to the hospital, who performed the operation, said that the light at which the dental syringe was warmed was fully six feet away from the operation table, there was no naked flame near. Within two or three seconds of the explosion bright red blood came from the patient's nose, and the whole apparatus burst into flames. Mr Cole explained that during the war 1,600 patients suffering from similar injuries passed through his hands, and what was done here was merely routine work. The explosion, he thought, must have arisen from the mixture of vapours he himself used the syringe, and satisfied himself that it was not red-hot. The teeth had been smeared with alcohol in order to make them perfectly dry, otherwise the dental cement would not adhere. The explosion occurred when the operation was practically over. He had never heard of such an accident before. Dr Niel McDonald, anaesthetist to the hospital, who gave the anaesthetic, said he had never come across anything like this before, nor had he seen any account of such a thing in surgical literature. Dr Angus Kennedy, who made a *post-mortem* examination, said that the cause of death was rupture of the bronchi and collapse of the lungs, there was no sign of burning in the mouth. The jury returned a verdict that the boy's death was an accident caused by the explosion. We understand that Dr McDonald intends to communicate a report of the case to the Section of Anaesthetics of the Royal Society of Medicine.

CHARLES BELL AND MODERN NEUROLOGY

At the opening meeting of the Section of Neurology of the Royal Society of Medicine, held at the Middlesex Hospital on October 8th, Dr H. Campbell Thomson gave his presidential address on "The work of Sir Charles Bell in relation to modern neurology." Dr Campbell Thomson began by pointing out that men of science were most often remembered by some particular discovery associated with their names, while the principles underlying such a discovery and the position the discoverers held with regard both to their predecessors and to those that followed were apt to be overlooked. Sir Charles Bell was no exception to this rule, and while his name is particularly associated with the functions of the spinal roots, his work was closely linked to what had been taught in previous times and also formed an important starting point for those who came after. Bell came from Scotland to London in 1804, and evidently found his first Sabbath in this city very depressing. He took a tumbling down house in Leicester Street, Leicester Square, and here founded his famous museum, which was purchased by the Edinburgh College of Surgeons in 1825. Bell's main interest at first lay in anatomy, but he soon realized the importance of function in relation to structure. In 1807, as shown by a letter to his brother, he was already on the track of the problem of nerves of sensation, and was considering the doctrine of the specificity of nerves. His work on this subject consisted at first in the examination of all the spinal nerves, in which their exact resemblance to one another was noted, and by experiment Bell showed that the two roots had different functions. The cranial nerves next received attention, it was the fifth alone which appeared to him to resemble the spinal nerves and be responsible for the double function of sense and motion. He particularly investigated the nerves of the face, and by experiments on an ass he was able to show a difference between the functions of the fifth and seventh nerves. The physiology of the nervous system at

this period was practically in the state in which it had been left by Galen, and there was intense antagonism in certain quarters to Bell's views, which, however, in the words of one of his contemporaries, "led to the entire remodelling of nervous physiology." Bell's accuracy of observation is well shown by his description of the hemiplegic's inability to raise the shoulder voluntarily while the paralysed muscles contracted during respiration, and he concluded that there must be a separate innervation for voluntary and involuntary movements. He also recognized the importance of muscle sense, and after confirming the observations of Meckel and Monro on the distribution of sensory nerves to muscles, he concluded that the impulses passing from the muscles to the central nervous system were essential for "the governance of the muscular frame." Bell anticipated the later discoveries connected with reciprocal innervation when he attached a weight to the tendon of an extensor muscle, and observed that the weight descended on the contraction of the opposing flexor muscles, to explain this he imagined the occurrence of peripheral inhibition. A certain amount of controversy has taken place over the part Bell took in differentiating the spinal roots, and in this connexion an address to the British Association in 1833 by Dr W. C. Henry was, Dr Thomson said, of great importance. In dealing with the then recently acquired knowledge of the physiology of the nervous system Henry stated that the honour of the discovery belonged "exclusively to Sir Charles Bell." He went on to say that Mayo had, by his study of the cranial nerves, been able to correct certain errors in detail in Bell's work, and Henry also disposed of Magendie's claims by pointing out that this worker had stated that his experiments were made without knowledge of those made earlier by Bell. Despite the fact that some of Bell's conclusions were incomplete or failed to stand the test of time, his work gave such an impetus to physiological research that he has been compared with Harvey. Bell's talents as an artist are well shown by the illustrations in his *Anatomy of Expression*, and his position as a surgeon was fully recognized. He was elected surgeon to the Middlesex Hospital in 1814, and he founded the medical school of that institution a few months before being invited to occupy the chair of surgery at the University of Edinburgh in 1835. During Dr Campbell Thomson's address certain of Bell's sketches, including "Sunday in Scotland" and "Sunday in England" and illustrations from his *Anatomy of Expression*, were shown by the epidiascope. His portrait and an interesting collection of sketches, books, and other relics were afterwards on view.

JAPANESE HEALTH ORGANIZATION, PAST AND PRESENT

If anything is needed to demonstrate the value of the League of Nations' organization for the interchange of study by medical officers of health, it will be found in the publication of thirty-six lectures¹ which have been prepared by various Japanese authorities for the instruction of medical officers of health from Far Eastern countries during an interchange study tour in Japan between October and December. These lectures cover the whole field of hygiene. Sanitary administration, water supplies, disposal of waste products, control of food, milk and beverage—serums and vaccines, mineral springs, patent medicines—opium and narcotic drugs, and the various branches of social medicine and social hygiene are not only described as they exist in Japan, but each subject is introduced by a most interesting and instructive account of its history in Japan from the earliest times. In the lecture on water supplies for example we are told that the existing waterworks in

Tokio are the oldest in the empire, and date back to the year 1590. Again, in connexion with food supplies we learn that animal meat was used as a food until the introduction of Buddhism some fourteen hundred years ago, when an imperial decree prohibited the eating of the meat of cow, horse, donkey, dog, or chicken—a prohibition which seems to have held good until the restoration in 1868. The whole series of lectures is full of curious and interesting information of this kind, and their publication by the League of Nations now provides those who may not have the good fortune to take part in the interchange study tour in Japan with a compendium of facts of an historical, scientific, and instinctive character which greatly enhances the admiration we already have of the work of the medical officers of that fascinating country.

THE "NEWELL TREATMENT OF TUBERCULOSIS"

This number of cures for tuberculosis submitted every year for public appreciation does not seem to diminish. As a rule, after a hectic career in the advertisement columns of newspapers and magazines, and even on omnibuses and hoardings, most of them cease to occupy any large place in the public eye. Some continue their career on a smaller scale of notoriety, others apparently disappear altogether. Last spring John Bull published some articles on the "Newell" treatment of tuberculosis. The treatment was to be administered by hypodermic injection, and it was announced that the medicament was to be supplied only to members of the medical profession. No indication was given as to its ingredients. A number of letters were received at the head office of the British Medical Association from medical men asking for information, but no satisfactory reply could be made as the composition of the remedy was not stated. Accordingly, on April 28th the Medical Secretary wrote to Dr J. Stenson Hooker, who, it was understood, was then acting as chairman of a committee of medical men which had been established to investigate the treatment. Dr Cox inquired what arrangements were being made to deal with the matter in accordance with the traditions of the profession. Dr Hooker, in his reply, said that the discoverer had asked that for the present the composition of the remedy should remain a secret, and added that "in view of the huge and vital issues at stake the committee and myself have agreed to grant this, to us, very reasonable request." This is the only foundation for a paragraph which appears in a pamphlet recently issued to the medical profession. The paragraph is "The British Medical Association, a short time afterwards [after April 2nd], wrote the Chairman of the Committee of Investigation asking for information concerning the movement, and that body was supplied with the information applied for." The information actually supplied was of the nebulous kind we have indicated, and nothing more was done at the time. On September 10th a notification was received to the effect that Dr Stenson Hooker had found "it necessary to transfer the supervision of the dispatch of the Newell treatment for tuberculosis to H. W. White, M.R.C.S., L.R.C.P., Chairman of the Medical Committee of Investigation, at 23, Fitzroy Square, London, W.1." It was added that Dr Stenson Hooker retained "the position of vice chairman to the committee and chief medical officer at the principal London clinic for treatment" in Spanish Place. The pamphlet referred to is entitled, "Treatise of the Newell Tuberculosis Treatment, for circulation to the Medical Profession only", in it we read that the sponsors for the Newell treatment "are dealing with something which is whole spheres above 'medical others'." The next section of the pamphlet professes to give the nature of the ingredients of the remedy. It is stated to contain five constituents. Of the first it is said that "it promotes healthy suppuration, or rather, healing suppuration", of the second, that it is

¹Health Organization in Japan. League of Nations—Health Organization—C. 11.332. (Pp. 230)

of a vegetable nature, a non-irritating tonic known to ancient writers, including Dioscorides and Pliny. The third constituent, it is said, is also vegetable, and was well known to the ancients, especially to the Egyptians. Of the fourth constituent it is stated that it is "a salt," that its employment is followed by leucocytosis and that it is a vaso-dilator. The tuberculi deposits soon become, the pamphlet states, infiltrated by the leucocytes and undergo fibroid degeneration, so that eventually the imprisoned bacilli and their products become disintegrated and rendered harmless. The fifth constituent is said also to be a vegetable and to act as a powerful stimulator to the liver and to aid the stomach in digestion. As will be seen from what has been said, and more fully from the pamphlet, there is here no disclosure of the nature of the ingredients of the alleged remedy. Another section is headed "Reasons for not divulging the exact nature of the formulae employed." These reasons are that the committee "are immediately, vitally, and successfully dealing with an immenso problem rather than spending our time and energy in theorizing first and healing afterwards," and that the ultimate verdict "must be given by the patients and the public in general." The pamphlet states that the committee is steadily compiling the results of the treatment, and proposes to publish them. Meanwhile it gives some samples which do not appear to rise above the testimonials which are very commonly given to any remedy for consumption newly advertised. It seems to us that medical practitioners can have no hesitation in making up their minds as to the course they should take, and the pamphlet itself, apart from what we have said, affords sufficient ground for a decision.

INCOME TAX

It is at this time of year that the general issue of notices of assessment is made, and medical practitioners are advised to examine these unwelcome documents closely and without delay. If the figures are not understood or the amount of the assessment is considered excessive, a letter should be sent at once to the inspector of taxes asking for further information or objecting to any particular figures, even in the former case it is sometimes advisable to state that the assessment is objected to because the twenty-one days allowed for the lodging of objections may be held to bar a future request for a reduction of the gross assessment. This applies more particularly to cases where the depreciation allowance authorized by this year's Finance Act can be claimed and has not been received. Personal allowances and reliefs for 1925-26 can be claimed at any time, within six years, but in this connexion also promptitude is desirable, the Inchequer is entitled to a sufficiently large share of a practitioner's earnings, it is quite unnecessary to inflate that share by procrastination or neglect.

THE MEDICAL PROFESSION AND THE ARTISTS' RIFLES

The close bond uniting the medical profession to the distinguished corps known as the Artists' Rifles is not generally known. In the old Volunteer days, long before the Territorial Army was organized, a company in the corps was composed entirely of medical students and doctors, Guy's and St Thomas's Hospitals providing most of its members. After a lapse of many years this bond has been restored by the presence of the Artists as the guard of honour when H.M. the King opened the British Medical Association House in Tavistock Square. The new building and the Artists' headquarters in Duke's Road are only, as the cron flies, about 150 yards apart. We understand that the corps needs recruits, and fathers with sons in London pursuing their medical or other professional studies might do far worse than urge them to join. Besides serious

military instruction, the corps affords opportunities (so hard to find in London) for every kind of sport, is well as an occasion for joining a "school of arms" with a record at the Military Tournament of which it is justly proud.

FILTERABLE VIRUSES.

VACCINIA AND VARIOLA

For some years the Medical Research Council has promoted researches into the nature and properties of the so-called filterable viruses and into the widely various and destructive diseases with which they are associated. One of the workers engaged in these researches is Dr Mervyn Gordon, F.R.S., who has carried out his investigations at St Bartholomew's Hospital. He has already reported research work on the virus of influenza, and three years ago addressed the Section of Bacteriology of the Annual Meeting of the British Medical Association on this subject. He found himself handicapped, however—partly owing to the irregular supply of material, partly by lack of knowledge of how to handle such organisms as the virus he had isolated, but chiefly by the difficulty in deciding whether the illness from which an experimental animal suffered after inoculation with this virus was true influenza or not. It was also often hard to say whether the experimental animals that showed no symptoms escaped through a natural or acquired immunity. Therefore he determined to concentrate his attention on a filter-passing virus that would produce an unmistakable lesion in a laboratory animal, and he chose vaccinia as the virus to study, in most of his experiments he used rabbits—animals which respond to inoculation with vaccinia virus by typical cutaneous lesions. Dr Gordon gave a preliminary account of his results to the Section of Pathology and Bacteriology of the Annual Meeting of the British Medical Association at Bath this year. His remarks were published in our issue of August 1st (p. 192), his full text is published in the report of the Medical Research Council now issued.

The report consists of three chapters, the first is a general introduction defining the object of the inquiry and giving an account of the work of previous investigators with regard to vaccinia and variola, it is accompanied by a long series of references to the literature. The second chapter describes and discusses Dr Gordon's own studies of vaccinia, and the third deals in the same way with his investigations of variola. The report is very well put together, each chapter being divided into sections with explanatory titles.

INTRODUCTION

The first thirty pages of the introductory chapter contain in a series of sections a condensed review of previous investigations along lines similar to those which Dr Gordon himself has undertaken, and form a valuable contribution to the literature of the subject. The new work reported in later pages was planned in the following way. Since the microscopic examination and conventional culture tests have presented great difficulties, Dr Gordon has confined himself to experimental work, and employed the skin of the rabbit as a "reagent" for detecting the presence of vaccinia virus, and succeeded in making his tests quantitative by submitting his material to a known degree of dilution before inoculation. The virus grows in the rabbit's skin, and he increased his stock of virus by scraping the lesions. Having standardized this method he embarked on the extensive research described in the next two chapters of the report. During the time that this experimental study of the virus of vaccinia was in progress, five outbreaks of small-pox in various parts of the country provided an opportunity of comparing specimens of the virus of variola with that of vaccinia. He was able, therefore, to extend the field of his investigations, and bring an already acquired expert method to bear on the important practical questions of the relation between vaccinia and variola and the comparison of the virus obtained from severe cases of small-pox with that from the milder cases sometimes referred to as *alastrum*.

¹ Medical Research Council Special Report Series No. 68. *Studies of the Viruses of Vaccinia and Variola*. By M. H. Gordon, M.D., C.B.E., D.M. F.R.S. H.M. Stationery Office. (Pp. 125 with 5 plates 1 in colour Price 3 6d net.)

STUDIES IN THE VIRUS OF VACCINIA

Using the shaved skin of a rabbit as an indicator for determining the presence of vaccinia virus, and working with tenfold dilutions of the pulp obtained from his living cultures, Dr Gordon set out, in the first place, to compare the relative potency of various specimens of calf lymph supplied in this country for purposes of vaccination. He observed great differences in the efficacy of these, some being active at a dilution of 1 in 100,000 and others only at 1 in 10. By cross-protection experiments he proved that the reciprocal immunizing action of these individual strains of virus was identical. He examined the value of certain disinfectants for destroying the virus of vaccinia *in vitro*, and noted in particular the exceptional capacity of potassium permanganate for destroying the virus, a capacity apparently superior even to that of mercuric chloride.

Effects of Heat

Studying the effect of heat, he found that while exposure of a suspension of vaccinia virus for thirty minutes to 55° C reduced the amount of living virus very greatly (the reduction amounting to over 99 per cent), in the case of strong suspensions some living virus could still be detected after the application of this amount of heat. In spite of the lethal effect of heat, however, he found that, provided the specimen of vaccinia virus was used in a fresh condition and was of good potency, this material, even after being heated for thirty minutes to 55° C, was quite capable of producing an excellent degree of immunity. Thus a rabbit so protected successfully resisted over 1,000 minimal vaccinal doses of virus. With the above mentioned reservations as to the source of the virus, he states that the full prophylactic effect could be obtained irrespective of the route by which the heated virus was administered, whether intracutaneous, subcutaneous, intravenous, or intrathecal. But temperatures higher than 55° C materially reduced the prophylactic efficiency. After subcutaneous injections of the virus immunity began to appear about the fourth day, and rapidly increased during the next two days. In ten days immunity was well established, and in a hundred days a decline was apparent.

Specific Antibodies in the Blood

The next step in this research was a study of the specific antibodies which appear in the blood of a rabbit after inoculation with vaccinia. Dr Gordon investigated three of these specific properties of immune serum—the complement fixing antibodies, the agglutinins, and the lysins. Both complement fixing antibodies and agglutinins appeared in response to injection of either raw virus, or of virus that had been heated for thirty minutes to 55° C, and these antibodies were found to be specific to the viruses of vaccinia and variola.

Having succeeded in demonstrating active immunity to vaccinia and in defining the specific antibodies in immune serum, he proceeded to ascertain whether the serum of rabbits immunized against vaccinia is capable of protecting others from this disease. This was accomplished without difficulty and a serum prepared, 1 ccm of which would protect against 100 minimal vaccinal doses of vaccinia virus. It is interesting to note that the behaviour of an antiviral serum resembles that of the better known antibacterial serums in that the titre of an immune serum in complement fixing and agglutinating antibodies is not necessarily an index of its protective value.

The complement fixing antibodies and agglutinins in antivaccinal serum can be used, not only to detect the presence of vaccinia virus in a given material, but also, within limits, to measure its abundance. Using these tests in conjunction with the more delicate cutaneous virulence test Dr Gordon showed that the virus of vaccinia is affected by gravity and may be spun down to the bottom of a tube by centrifuging. After passing a suspension of vaccinia virus through the Beilfeld filter all three indices were negative—namely, cutaneous virulence test, complement fixation and agglutination. In some later experiments however a portion of the virus passed through a Beilfeld filter so that it seems that in certain circumstances the virus is filterable. The conclusion to be drawn from these experiments is that the virus of vaccinia is certainly particulate.

Susceptibility of Nasal Mucosa

In testing the permeability of various surfaces of the rabbit to the virus of vaccinia Dr Gordon found that the virus of vaccinia can make its way through the nasal mucous membrane, the ocular conjunctiva, or the external auditory canal, and produce immunity. Under natural conditions, and in the complete absence of trauma, the nasal mucosa is by far the most susceptible and permeable to the virus of vaccinia. When a small quantity of potent lymph was planted on the nasal mucosa, the rabbit, after an incubation period of six to eight days, developed a condition of acute nasal catarrh, indistinguishable in appearance from that of acute "cold in the head" in the human subject. The virus of vaccinia appeared to be very plentiful in this acute nasal discharge, especially at the onset. Later catarrhal bacteria, such as pneumococci, could be found in films stained in the usual manner. Dr Gordon draws attention to the importance of these observations in a paragraph we quote from page 135 of the report:

"The pronounced susceptibility of the nasal mucosa of the rabbit to the virus of vaccinia and the acute attack of nasal catarrh that follows after an incubation period when this virus has gained access to its nasal mucosa are matters that serve to raise the question whether the main natural mode of spread of this bovine disease may not be in part by the respiratory tract rather than entirely by fortuitous cutaneous inoculation as hitherto supposed. As it is evident that the disease which we call vaccinia is linked up to the group of influenza and acute nasal catarrh by this observation, further information is desirable as to the natural distribution and mode of spread of vaccinia virus in the animal kingdom. Such an investigation can be advocated with the more confidence since we possess a triple index whereby to identify the presence of vaccinia virus and to estimate its abundance."

STUDIES OF THE VIRUS OF VARIOLA

It was mentioned above that the occurrence of outbreaks of small-pox in this country gave Dr Gordon an opportunity of extending his researches to variola virus. He compared the viruses of alastrim. He writes:

When an attempt was made to obtain specimens of the virus of variola for investigation however it was found that cases occurring in this country and included at present in the general returns as small pox are clinically of two different types. It would seem that nowadays the classical form of variola with its clinical severity and high mortality among the unvaccinated is comparatively uncommon; the bulk of the cases now occurring being instances of a benign form of the disease known elsewhere as alastrim in which while the general features are those of small pox the malady is generally mild, the almost uniform tendency of the affected even when not previously vaccinated being towards recovery. As alastrim appears to breed true this vast difference from typical small pox as regards severity has caused the question to be raised as to whether alastrim may not be due to a different virus from that producing the severe type of variola, and Garrow has even gone so far as to suggest chiefly on epidemiological and clinical grounds that the two diseases are in fact different, and that this mild type of variolous disease should be called paravariola.

From the experimental point of view the issue presented by alastrim may be put as follows: Is the virus of alastrim merely an attenuated strain of variola or is it specifically different after the manner that varicella apparently differs from variola? Since the chief object in taking up the study of variola virus was to compare its qualities with those of vaccinia in the following experiments specimens of the virus both of alastrim and of the severe type of variola have been compared with that of vaccinia. Although the relationship of alastrim to variola and varicella was not the primary object of study but rather the relationship of all three to vaccinia some of the information obtained has a direct bearing on the question formulated above.

The material that has been submitted to investigation came from five outbreaks of small pox three of which were instances of alastrim and two of the severe type of variola.

The alastrim material was obtained from Gloucester (1923), Chesterfield, and Ashington. Material was also obtained from a case of confluent small pox in Surrey, and from a small but fatal outbreak at Willesden.

Inuses of Alastrim and Confluent Small-pox

Dr Gordon compared the viruses of alastrim and of confluent small-pox as regards pathogenicity, immunity relative to vaccinia, and resistance to heat and disinfectants. Both the virus from alastrim and that from confluent small pox were found to be inactivated by exposure for half an hour to 55° C, and both viruses were destroyed by potassium permanganate at a dilution of 1 in 10,000. Animal experiments with virus obtained from cases during the Gloucester outbreak of alastrim showed that the virus of the Gloucester outbreak had some protective effect against vaccinia.

Rabbits and monkeys were inoculated cutaneously both with the virus of variolium and confluent small-pox. Neither virus affected the rabbit, but both gave positive results in the monkey, producing a local papulo-vesicular lesion which was more severe with the virus from the case of confluent small-pox than with that from the milder type of the disease. Particularly important is the fact that vaccinia was found to protect the monkey against both these forms of variolium virus, and the action was found to be reciprocal, but Dr Gordon noted that the degree of protection afforded by vaccinia against vaccinia was inferior to that afforded by vaccinia against variolium. Neither of these forms of variolium virus was found capable of affording any pronounced degree of protection to the rabbit against vaccinia. In the future perhaps some of the laboratory reactions which are described in this report may come to have a practical application in the diagnosis of small-pox, especially in doubtful cases where such help is most needed. This likelihood is suggested by the fact that antivaricellal serum prepared from the rabbit was found to give a positive result, both in the complement fixation test and in the agglutination test with material from all of five outbreaks of variolium, three of which were examples of the alastrum type and two of the severe type of the disease.

Some control observations were carried out with material obtained from cases of varicella. This virus proved inert when inoculated cutaneously into either the monkey or the rabbit. Material also from six outbreaks of varicella when examined with antivaricellal serum by the complement fixation and agglutination tests gave in all cases a negative result.

By none of the tests which Dr Gordon employed could any difference be detected between the virus of the mild or alastrum type of small-pox and the more severe type of this disease, except in regard to virulence to the monkey. Jenner also held that the mild and severe small-pox were one and the same disease, as is proved by some striking quotations from his writings which Dr Gordon supplies on pages 106 and 107 of this report.

CONCLUSION

In conclusion it may be observed that this report carries our knowledge of virus diseases appreciably forward. By his accurate quantitative technique and by the definition he has given to experimental and serological tests, Dr Gordon has not only cleared up many doubtful points with regard to vaccinia virus, but has provided reliable methods which may be advantageously used in the study of other virus diseases. His observations on the relations of alastrum and confluent small-pox, though they do not decide all the debatable points which have recently arisen, are forceful arguments and promise that if the accurate methods he has devised were employed in a large series of cases some of the outstanding problems might soon be solved.

VOLUNTARY HOSPITALS IN GREAT BRITAIN

SIXTH ANNUAL REVIEW

Dr F. N. KAY MENZIES, director of hospital services, Joint Council of the Order of St John and the British Red Cross Society, has issued a sixth annual report on the voluntary hospitals in Great Britain, excluding those of London. The report contains sixty tables analysing the hospital position in the provinces and Scotland, and Dr Menzies also reviews, in the light of the statistical records, the recent recommendations of the Voluntary Hospitals Commission.

Hospital Statistics for 1924

Of the 793 voluntary hospitals in Great Britain outside London all but 38, and those quite small institutions, are covered by the review. The figures show a steady increase in the number of in-patients and a quite noticeable increase in the number of out-patients, the number of new in-patients treated during 1924 in the 749 hospitals which gave this detail was 614,609, and the number of new out-patients 2,496,485. The pressure on the large hospitals (those with 100 and more beds) has reached a point at which

over 88 per cent of the beds are kept in constant occupation. In the 14 medical school hospitals in England and Wales, where the average occupation reaches almost 90 per cent, approximately 20 patients are treated in each bed annually. In 605 hospitals in England and Wales, 420,000 surgical operations under general anaesthetics took place last year, and in 79 hospitals in Scotland 80,181 such operations. The increase in out-patient work, though most pronounced in the ophthalmic and renal departments, has been, with the exception of venereal work, a general one. One fact brought out is that the ratio of out-patient to in-patient work decreases in the general hospitals and increases in the special hospitals as the institutions become smaller.

The Financial Position

The financial totals are best set out in the following form

	Ordinary Income	Extraordinary Income	Ordinary Expenditure	Extraordinary Expenditure
England and Wales (662 hospitals)	£ 4 510 667	£ 1 655 182	£ 4 526 182	£ 1 216 524
Scotland (93 hospitals)	£14 692	£99 031	£69 374	£48 407
Totals	£7 999 772		£5 760 487	

Ordinary income failed to meet ordinary expenditure by just under £40,000, but 61 per cent of the hospitals had a surplus on ordinary income. Extraordinary income in the table includes receipts for capital purposes, and extraordinary expenditure includes expenditure of capital. The total amount received in legacies was £1,175,427, of which about 20 per cent was earmarked. In Scotland free legacies were more than sufficient to pay half the ordinary expenditure.

In England and Wales an increase in workmen's contributions is shown all along the line. The income from this source, including the Hospital Saturday Fund and contributory schemes, was £1,249,153, an increase of about £157,000 on the year before. Patients' contributions (£644,214) and payments by or on behalf of patients (£1,022,894) show on the whole a very slight decrease, and the income received from public services remains very much the same (£378,680). Subscriptions (£638,203) have slightly increased, and donations (£719,253) rather more noticeably diminished. The expenditure per available bed in the case of 594 hospitals giving details averages nearly £107 a year, and in Scotland, for 93 hospitals, £115 a year. A curious difference is noted between the average annual cost per occupied bed in the English group of medical school hospitals (£182), and the corresponding figure for the Scottish group (£143), but the English hospitals with medical schools treat approximately twice as many out-patients per occupied bed as the Scottish. In Scotland workmen's contributions (£178,184), patients' contributions (£53,475), and payments by or on behalf of patients (£108,145), all show slight increases. The amount received from public services (£54,670) has declined a little, and is £3 less per available bed than in England. Donations are well maintained, but subscriptions show an almost constant fall during the last five years. Since 1920 the Scottish hospitals have increased their invested funds by £1,500,000, compared with an increase during the same period of £3,500,000 for the hospitals of England and Wales.

Recommendations of the Voluntary Hospitals Commission

The Voluntary Hospitals Commission has estimated the number of additional beds now needed to be 10,000 in England and Wales including London. Dr Menzies estimates that the capital expenditure involved in this provision will be £5,000,000 and the annual maintenance cost £1,250,000. It would probably require five years to build, equip, and staff the accommodation represented by these additional beds. Can the hospitals, without State aid, undertake this obligation? During the last four years the average annual increase of beds in the voluntary hospitals of England and Wales including London, has been 1,350. This is an abnormal figure, and Dr Menzies thinks the

¹ *British Medical Journal*, August 15th, p. 265.
Including the 118 hospitals in London the total voluntary hospital provision in Great Britain is 911 hospitals with 59,551 available beds.

normal increase may be placed at 1,000. Thus about half the additional beds which the Commission considers necessary will be forthcoming during the next five years from the ordinary financial resources upon which voluntary hospitals rely for their support. With a view to avoiding the necessity for a large Government grant, several suggestions have been made in the press, such as a closer co-operation between hospitals, relief from local rate charges, and exemption from legacy duty. Dr Menzies says that the first of these is an ideal which has proved in practice almost unattainable, and he gives reasons for thinking that the other suggestions are not likely to find acceptance with the municipal and State authorities. A desirable development would be the institution of a central fund for provincial hospitals, similar to King Edward's Hospital Fund for London, but such a scheme would take time to mature, and the present need is urgent. He believes that the maintenance cost of £1,250,000 a year for these additional beds would be found by the supporters of voluntary hospitals as and when required—in a foreword Sir Arthur Stanley does not seem to share his optimism—but that the Voluntary Hospitals Commission, in view of certain economic facts, and especially of this additional maintenance burden, is thoroughly justified in recommending the Government to make a substantial grant towards the huge capital expenditure.

Special Hospital Problems

Some interesting articles are appended to the report, including one by Mr H. S. Souttar, who urges the need for hospital provision for the middle class, either by the provision of special hospitals or—a more practicable proposition in the absence of assistance from the State or from generous donors—of paying wards in voluntary hospitals.

Mr Bishop Hamman, in another article, sets out the advantages and disadvantages of general hospitals with special departments as against special hospitals set up for the diagnosis and treatment of certain particular diseases. His conclusion is in favour of the general hospital with a range of special departments covering all modern requirements. He makes certain exceptions in favour of the special hospital, but he thinks there is no justification for separate hospitals for many of the conditions or the special treatments for which these at present exist, and that the need is better met by departments in, or in association with, a general hospital, which is the ideal unit of hospital organization.

MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY

The annual general meeting of the Medical Sickness, Annuity, and Life Assurance Society was held at the offices of the company, 300, High Holborn, W.C., on October 12th, when Dr F. J. ALLAN was in the chair.

CHAIRMAN'S ADDRESS

The chairman congratulated the members on the satisfactory report which the directors were able to present on the work of the company during the past year. He pointed out that while the business of the society had increased the ratio of expenses showed a decrease of nearly 2 per cent as compared with the previous year. Referring to the foundation of the society, he said it was the first and pioneer to initiate the system of insurance against sickness. It was founded largely through the exertions of the late Mr Ernest Hart, Editor of the BRITISH MEDICAL JOURNAL, who was led in 1883 to undertake the work through numerous letters received from members of the profession, pointing out the hardships which medical men and their families suffered during illness. The scheme adopted was to provide a weekly sum which would cover the extra expenses which illness entailed, and loss of income should the illness be prolonged. An important feature, however, was that if the illness became permanent the payment was continued up to the age of 65 years. This had been found very valuable by many who became incapacitated, and in some instances it constituted the sole income of the recipient. It was hoped that in the meantime members would have taken out an annuity policy for the rest of their lives and thus compensate for the cessation of sickness pay at 65. The society was now paying over £5,500 a year to those who had done so. With regard to life insurance the society, in its earlier days, was registered under the Friendly Societies Act which limited the amount of insurance to £300. This restriction prevented

the society from giving benefits which many medical men wanted, and eventually, in 1920, it was converted into a limited company on a mutual basis, since when it had been able to extend its sphere of operations in many directions for the benefit of the medical and dental professions. The careful way in which the finances of the society had been handled had led to the building up of a fund invested in first class securities, which would enable it to meet any claim which might arise without any strain on its resources. The funds for the sickness and accident insurance had been kept entirely distinct from those of the other branches of insurance, and recent events had proved the soundness of his procedure. In explaining why the society was able to offer better terms for sickness and accident than other companies, Dr Allan said that it had no dividends nor agents' commissions to pay. The society could now offer many different methods of sickness insurance to meet varying requirements. The scheme for newly qualified practitioners was proving a success, and consideration was continuously given to plans for future developments. The board of directors met weekly, or oftener if necessary, and gave individual attention to each proposal. The directors, representing as they did all branches of the medical and dental professions, were able to appreciate risks which could not be done by companies whose boards consisted of lay members. Since the reorganization of the life insurance branch in 1920 over £500,000 of new business had been transacted. The combined policies covering sickness, accident, and life assurance were becoming increasingly popular, as was also the educational policy of the society which included provision for a member's widow should the father die.

The chairman concluded his address by moving the adoption of the report. The motion having been duly seconded was carried unanimously.

Dr F. C. Muttley and Sir William Willcox were re-elected to the board of directors and Messrs Harber, Sturges and Fraser were re-elected auditors.

On the motion of the CHAIRMAN, a vote of thanks was recorded to the manager and staff generally for their excellent work during the past year.

Sir WILLIAM WILCOX moved a vote of thanks to Dr Allan for presiding and for the admirable work he had done for the society. The motion was carried, and the CHAIRMAN's reply concluded the proceedings.

England and Wales.

LIVERPOOL MEDICAL INSTITUTION JUBILEE MEMBERS
A SPECIAL general meeting of the Liverpool Medical Institution was held on October 8th to congratulate Drs A. Craigmyle and A. C. E. Harris and Mr Frank T. Paul on the attainment of their jubilee year of membership of the institution. The president, Mr R. C. Dun, and Mrs Dun received the members, and visitors and ladies were specially invited to be present. After tea, the assembly met in the theatre. The secretary read letters of regret from those unable to be present, and the president proposed in grateful terms a resolution of congratulation by the president, council, and members to the three members who celebrate this year their fiftieth year of membership.

Dr Alexander Craigmyle

Dr Richard Caton, emeritus professor of physiology, in support of the resolution, said that he had first met Dr Craigmyle, an Aberdonian graduate in arts and medicine, with a distinguished career as a student, when he was appointed house-surgeon at the Northern Hospital. There Dr Craigmyle at once revealed himself to be an assiduous officer, indefatigable in his duties and most considerate to the patients under his care. What he was as a young house-surgeon, he continued to be in practice in Wallace, where he was for many years among the leading practitioners of that growing community. Fifty years was a considerable span of human existence, but looking at Dr Craigmyle, who was now living in retirement, he could not help remarking on his vigour, and wished him health and happiness to enjoy the ease he had so meritoriously earned.

Mr Thelwall Thomas called to mind his first acquaintance with Dr Craigmyle for whom he acted as locum tenens. He was impressed with the student character which Dr Craigmyle displayed throughout his long career of medical practice. He was medical officer of health for Wallace, one of the founders of the Victoria Central Hospital, and

for many years one of the honorary surgeons attached to it. Dr Crugmille's public services were well known in the borough of Wallasey. Mr Thelwall Thomas touched upon his private life in most appreciative terms, a true friend and a helpmate to many of the young medical men who settled in the rapidly growing district of Cheshire. Although no longer residing in Wallasey, Dr Crugmille had left behind a memory of kindness towards his colleagues which they would ever cherish and of high esteem among those who were his patients.

Dr Crugmille expressed his sincere thanks for the honour that had been paid him, and his unfeigned pleasure in being a member of the institution which he joined shortly after coming to Liverpool. Speaking of his house-surgery in Liverpool, he stated that almost all the cases of compound fracture died of septicaemia. This was before the introduction of Lister's antiseptic system with its attendant the change was remarkable. He remembered well the removal of a loose body from the knee joint carried out under strict Listerian principles, which was crowned with success, much to the joy of those who had care of the case. He would always look back upon that day as a memorable one in his life, he valued highly the all too kind terms in which his friends had thought fit to characterize his life's work.

Dr A C E Harris

Sir James Barr regretted that Dr Harris was not able to be present to receive the congratulations of the members, but Mrs Harris, who was present, would be able to convey to her husband the high esteem and affection that his professional brethren had for him. He recalled the first time he met Dr Harris, who had settled in practice in Birkenhead, a friendship begun in 1874 had remained untroubled up to now. He spoke feelingly of the loveliness of Dr Harris, his never-failing courtesy, and his sound knowledge of clinical medicine. Singularly void of self-advancement, self-abnegation, it could be truthfully said, was his characteristic. He had filled the office of vice-president, and the presidency had been offered to him on more than one occasion. He was president of the Birkenhead Medical Society, and in the midst of his professional work took a keen interest in public affairs. He was a member of the borough council of Birkenhead, and at one time chairman of the Education Committee. Since 1894 Dr Harris had been a magistrate, and evinced on the bench those painstaking qualities which had ever been his characteristic as a medical practitioner. In Birkenhead he had endeared himself to his fellow practitioners by his transparency of purpose and sincerity of heart.

Dr Edgar Stevenson seconded the resolution, and in fitting terms dwelt on the personal attraction of Dr Harris. He recalled his first meeting with him and the impression left upon his boyish mind. It was not to be wondered at that Dr Harris had gained a place in the esteem and affection of all with whom he came into contact.

Mr Frank T Paul

Mr Rushton Parker, professor of surgery, gave his reminiscences of Mr Frank T Paul, who in 1873 came to Liverpool to fill the newly created post of resident medical officer to the Royal Infirmary. Mr Parker traced rapidly his further progress, not only as a teacher in the then Royal Infirmary School of Medicine, but as a surgeon, and the world-wide reputation he enjoyed as a pioneer in abdominal surgery.

Mr Thomas H Bickerton, consulting ophthalmic surgeon in seconding the resolution, gave an account of Mr Paul's life during the past fifty years. He enhanced his remarks with personal touches, alluding to Mr Paul's recreations: he was a skilled canoeist and yachtsman who had gained prizes in racing events, an interesting and informative companion in a country ramble, an excellent photographer, horticulturist, cricketer, cyclist, and motorist. His serenity stood him in good stead, both when a work and at play. Equanimity was ever retained in the most trying circumstances. A consummate pathologist, morbid anatomy, naked eye and microscope was the sure foundation on which his surgical skill was built. It was not a matter of surprise that his fame as a surgeon was world-wide. Paul's tube would always keep his memory

green in abdominal surgery. As a teacher he was clear and precise, careful in statement and master of the subject on which he was lecturing. The microscopic specimens cut by his own master hand, and distributed to the students whom Mr Paul was lecturer on histology, are in the possession of many of his former pupils—a living testimony to his skill. Mr Paul practised the antiseptic method from the very outset, previous to this all the cases of hernia during the first year he was at the Royal Infirmary died. Mr Bickerton, in conclusion, said that if he had to choose a motto for his friend, and one that had characterized all his actions, it would be "Let all things be done decently and in order."

Mr Paul expressed his great appreciation of the honour the members had bestowed upon him in assembling to congratulate him on his fifty years' membership. Dr Crugmille and Harris were old friends, and his pleasure was enhanced by the fact that they shared in those congratulations. Mr Paul gave an interesting review of his activities, and mentioned that one of the very few honours he craved about was to become president of the Liverpool Medical Institution (1906-1908). In his retrospect he paid a high tribute to the education he received at Guy's Hospital. There he acquired a good experience in several branches, ophthalmology, laryngology, and minor surgery and dentistry. His love of the country and outdoor pursuits he attributed to his happy childhood, which was lived in the country in Norfolk. Upon his colleagues at the Royal Infirmary, where Mr Paul was on the active staff for twenty years, he bestowed grateful words of appreciation of their help and steadfast friendship. The great war brought him into contact with many other surgeons at Fazakerley Hospital, and thus he was able to cement new ties of friendship. In conclusion, Mr Paul said that he was much indebted to his professional brethren in the various acts of kindness that he had received during his active life. He still hoped to continue his surgical work at the cottage hospital to which he had been appointed as operating surgeon.

A great surprise awaited the members when Mr Keith W Monsarrat asked Mr Thelwall Thomas to present Mr Frank Paul with a birthday gift. This took the shape of a volume of the most important surgical papers Mr Paul has written during the past fifty years. The leading surgeons in Liverpool and neighbourhood had combined to give a tangible token of the high esteem in which they held Mr Paul, and took advantage of this opportunity of presenting him with a copy of his works. The copy, which is to be handsomely bound, unfortunately was not ready. Mr Paul replied, and was much pleased with the signal honour his colleagues had shown him.

THE ANNUAL MEDICAL SERVICE IN LIVERPOOL

The annual medical service in Liverpool will take place on Sunday, October 18th, at 3 p.m. in the Cathedral. Members of the medical profession, who are requested to wear academic dress if possible, and their friends should be seated not later than 2.40. Tickets for the service can be obtained from Dr John Owen, 13, Rodney Street. The offertory will be in aid of the Royal Medical Benevolent Fund. It is hoped that the attendance will be a large one. Any medical man who may be prevented from being present can forward a donation to the local honorary treasurer, Dr J Ernest Nevins, 32 Princes Avenue, who will gratefully acknowledge its receipt.

LEEDS GENERAL INFIRMARY NEW RADIOTHERAPEUTIC DEPARTMENT

By the generosity of two donors—Mr J B Syles of Horbury, near Wakefield, who has presented the building, and Miss Walker, Newton Hall, Chapelton, Leeds, who has presented the artificial sunlight apparatus—the General Infirmary, Leeds, is now possessed of one of the largest and best departments of its kind in this country. The new building measures over 100 ft by 45 ft, and contains eleven treatment rooms, as well as a workshop and instrument, waiting, staff, and dressing rooms. The building is very airy and well lighted, and a broad corridor down the centre provides access to the various rooms. Five of the treatment rooms are devoted to deep x-ray therapy, and

each cubicle is equipped with apparatus capable of generating 200,000 volts and upwards. Provision is made for the housing of the apparatus in a large instrument room. Special care has been taken to provide for the adequate protection of the staff by heavy lead linings in all the cubicles, and the controls are placed in a special room outside without any reach of the operator. The cubicles are lofty, and are lit from above, while central heating has been adopted throughout the building. The artificial sunlight department consists of six treatment rooms. The two largest, measuring 20 feet square, will be for men and women respectively. Dressing rooms are attached to each, and an observation room is provided so as to control both treatment rooms. Each room is equipped with two "mountain sun" mercury vapour lamps and two arc lamps, together with special radiant heat lamps. A separate room for the treatment of patients unable to sit or stand is equipped with lamps which can be used while the person reclines on a couch. Another room is reserved for children, and similar equipment of arc and mercury vapour lamps has been provided here. A special room for treatment by the Kromayer lamps is placed at the end of the long corridor, and one of the largest rooms has been set apart for Finsen light treatment of lupus and similar diseases. At present, upwards of one hundred cases a day have been receiving artificial sunlight treatment, but the new department will be able to deal with upwards of three hundred.

Scotland.

POST-GRADUATE WORK IN GLASGOW

FROM November to May weekly demonstrations in medicine, surgery, obstetrics, and various special subjects will be held at different hospitals in Glasgow, on Wednesday afternoons. An inclusive fee of three guineas is payable for attendance. The Glasgow Eye Infirmary has arranged three special courses. A course for medical practitioners on the diagnosis and treatment of external diseases of the eye will be held on Tuesdays and Fridays, from October till December, and a practical course for ophthalmic surgeons on the use of the binocular microscope and slit-lamp is being arranged for October and November on days to suit the convenience of those participating. From January to May a course qualifying for the diploma in ophthalmic medicine and surgery of the Royal Colleges of Physicians and Surgeons of England will be given. A limited number of clinical assistantships are available for graduates who wish to study in detail one or other of the specialties, such graduates must enrol for a period of three months. This provides exceptional opportunities for those who wish to specialize, and for practitioners from overseas. A copy of the syllabus and further information may be obtained from the secretary of the Post-Graduate Medical Association, the University, Glasgow.

ANNUAL REPORT OF REGISTRAR-GENERAL FOR SCOTLAND

The seventieth annual report of the Registrar-General for Scotland, dealing with the year 1924, has just appeared. The population of Scotland at the middle of the year is estimated as 4,881,637, being 19,463 less than that of the previous year. The decline is attributed to the numbers of people emigrating in recent years.

Births and Marriages

The number of births registered in Scotland during the year was 106,900, which is the smallest number of births registered in Scotland since 1860, with the exception of three of the war years, 1917, 1918, and 1919. The births are 5,002 less than those of the previous year, and 11,700 less than the mean of the numbers for the preceding five years. The birth rate of the year was 21.90 per 1,000, which is 0.93 less than that of the previous year, 2.43 less than the mean of those of the preceding five years, and 1.64 less than the mean of those of the preceding ten years. The illegitimate children registered during the year numbered 7,085, which is the smallest number yet recorded. The marriages recorded during the year numbered 32,352, which is 2,848 less than in the previous year.

Deaths

The deaths registered during the year numbered 70,357, which is 7,074 more than in the previous year, 1,212 more than the average number registered in the preceding five years, but 1,584 less than the average number registered in the preceding ten years. The number is greater than that of the years 1923, 1921, 1920, and 1917, but is still less than a number of other years subsequent to 1868. The infantile mortality rate of the year was 97.7 per 1,000 registered births, which is 18.8 more than that for the previous year, which had, however, the lowest recorded rate. This is the sixth year in which the infantile mortality rate has been less than 100.

With regard to causes of death, out of the 70,357 persons who died during the year, 35,168 were males and 35,189 were females. The deaths of males numbered 3,486 more than in the previous year, and those of females numbered 3,588 more than in the previous year. The general Scottish death rate for the year was 14.41 per 1,000, which is 1.50 more than that of the previous year, and 0.23 more than the mean of those of the preceding five years, but 0.48 less than the mean of those of the preceding ten years. The maximum death rate (23.58) occurred in Scotland in 1864, and from 1855 to 1890, with the one exception of the year 1856, the national death rate has been constantly over 20 per 1,000, and from 1891 to 1893 over 19 per 1,000. It fell below 18 for the first time in 1894, below 17 in 1896, below 16 in 1909, below 15 in 1916, below 14 in 1921, and below 13 in 1923, with a slight rise in the year under review. Of the total number of deaths, 54 per cent were registered in the larger burghs. In the whole of the death rate was 15.83, while in the smaller burghs it was 13.18, and in the county districts 12.96. In the larger burghs, taken individually, the uncorrected death rate varied from 18.3 in Perth, 17.0 in Anstruther, 16.8 in Paisley, 16.7 in Dundee, 16.5 in Glasgow, 16.1 in Edinburgh, to 13.7 in Dunfermline, 12.5 in Kilmarnock, and 7.6 in Clydebank. In five of these burghs (Dunfermline, Clydebank, Kilmarnock, Perth, and Aberdeen) the corrected and adjusted death rate was lower than the national death rate, while in eleven it was higher. Of the total number of persons who died, 24.2 per cent were children of less than 5 years of age, and 36.8 per cent were aged 65 and over. The deaths of children of less than 1 year numbered 10,446. These deaths numbered 1,621 more than in the previous year. The infantile mortality rate of 97.7, although higher than that of the year 1923, and also of the years 1921, 1920, and 1916, is lower than in all other previous years since 1855. It had reached a maximum of 138 in 1897, but since 1915 had been only three times over 100. The oldest person whose age has so far been verified in Scotland died during 1924 at the age of 106 years 213 days; the age was verified by reference to an old parochial register. The previous oldest, in both cases females, had been aged 106 years 194 days. So far careful investigation has verified in all 95 instances of attaining to the age of 100.

Infectious Diseases

Deaths from enteric fever numbered 34, which is the smallest number of such deaths yet recorded in Scotland. For the first time no deaths from typhus fever were registered in Scotland, and in 1924, as in the two previous years, 1922 and 1923, there had been no deaths from small pox.

Measles was responsible for 1,592 deaths, which were 471 more than in the previous year. These deaths constituted 2.26 per cent of the total deaths and equalled an annual death rate of 33 per 100,000. In the larger burghs it equalled 46 in the smaller burghs 20 and in the county districts 20. The persons dying were chiefly children up to the age of 5 years.

Scarlet fever caused 410 deaths, which is the largest number since 1916 and 58 more than in the previous year. The number, however, is small compared with the numbers in the earlier years of registration. From 1855 to 1876 these deaths almost constantly numbered over 2,000 annually and were at a maximum in 1874, with 6,321 deaths. The first year in which deaths from scarlet fever numbered less than 1,000 was 1855, and the first in which they fell below 500 was 1903. The smallest number dying from this cause in any one year was 163 in 1918.

Whooping cough was responsible for 1,625 deaths (757 males and 868 females). The number was 636 more than in the previous year and the largest number of deaths from this cause in any year since 1917. Of the total number dying from whooping cough 43.5 per cent were children of less than 1 year old and another 51.4 per cent were children of between 1 and 5 years of age. The months of the year in which the greatest

number of deaths from whooping-cough were March, December, and April.

Diphtheria was responsible for 442 deaths, or 50 less than in the previous year, making a death rate of 9 per 100,000, which rate is the lowest yet recorded from this cause.

Influenza was responsible for 2,490 deaths, which is 1,959 more than in the previous year.

Tuberculosis accounted for 5,653 deaths, or 137 fewer than in the previous year. This is the smallest number of deaths from tuberculosis yet recorded in Scotland, the previous minimum being 5,737 which occurred in 1921. The maximum number of deaths recorded from this cause was 13,027 in 1870, and compared with this maximum year the year 1924 shows a reduction of 56.6 per cent. Of the deaths from tuberculosis 3,887 were due to tuberculosis of the respiratory system, which is 103 less than in the previous year, and the least number yet recorded in Scotland from this cause.

Cancer and other forms of malignant disease caused 6,498 deaths, or a death rate of 133 per 100,000. Both the number of deaths and the rate are the highest yet recorded. The death rate from this cause has risen steadily from 42 per 100,000 in 1870 to 49 in 1880, 54 in 1890, 74 in 1900, 93 in 1910, and 113 in 1920. In 1921 and 1922 the death rate was over 120 while in the last two years it has been over 130. Of the total deaths from cancer 2,867 were among males and 3,631 among females. The most frequent sites of fatal malignant disease were in males, the stomach, intestines, rectum, liver, oesophagus, prostate and tongue, while in females they were the stomach, breast, intestines, uterus, liver, and rectum.

Syphilis was the stated cause of death in 151 instances, which is 17 less than in the previous year. These deaths equalled a death rate of 3 per 100,000, which is the same as in the previous year.

Diseases of the nervous system accounted for 8,668 deaths of which 5,983 were due to various forms of apoplexy.

Diseases of the circulatory system accounted for 8,405 deaths, of which 7,339 were due to diseases of the heart. Diseases of the respiratory system, other than tuberculosis, caused 12,082 deaths, which is 2,991 more than in the previous year. These included 4,480 deaths due to bronchitis, 3,541 to bronchial pneumonia, and 3,165 to lobular pneumonia. The total pneumonia deaths of 7,691 equalled a death rate of 153 per 100,000, which is 59 more than in the previous year. A maximum pneumonia death rate had occurred in the year 1918 at the rate of 238 per 100,000.

Deaths attributable to violence numbered 2,589, which was 130 more than in the previous year. Of these, 2,205 were due to accident, the chief cause being burns or scalds in 330 cases.

The report deals with the vaccination of children born during 1923, who in ordinary course should have been vaccinated during that year or during the first half of 1924. The children born in the year 1923 numbered 111,916, of whom 7,611 died before reaching the statutory age for vaccination (6 months). Of those surviving that age (104,305), 64,659, or 61.99 per cent, were either certified as having been successfully vaccinated, or were reported as being susceptible to vaccination, while 38,815, or 37.21 per cent, were reported to be unvaccinated at the end of the year 1924. The majority of these 32,451 were unvaccinated by reason of a declaration of conscientious objection on the part of parents. The percentage thus remaining unvaccinated through parental conscientious objection formed 31.11 per cent of the total children. This percentage of conscientious objection varied from 84.1 per cent in Shetland to 8.9 per cent in Wigtown, 9.5 per cent in Peebles, and 9.6 in Nairn, while in Aberdeen the percentage was 8.6, in Edinburgh 20.8, and in Glasgow 22.9.

Correspondence.

POETRY AND PHYSIC

SIR.—The very interesting and scholarly address recently delivered by Sir Humphry Rolleston, a summary of which is given in your issue for October 10th (p. 660), is so suggestive that he must be held primarily responsible for this attack upon your space.

The address is a plea for the cultivation of poetry by our own profession. Non-poetry has suffered and still suffers from being so much read but so little heard. Its primary appeal is not to the eye but to the ear, a fact better appreciated in the dawn of the art than it is now. It is a pity that we have no class in these days corresponding with the sharpshooters, who of old were so successful in popularizing the poetry of their own time. What is wanted as a first

step towards the wider appreciation of poetry is not so much to read more as to hear more.

The cultivation of poetry by the medical man and scientist is of both utilitarian and æsthetic value. "Imagination," says Sir Humphry, "is a necessary stimulus to really good work, especially in original research." It may well be that the mental myopia induced by the narrow scrutiny of minutiae of facts is responsible for the dearth of great generalizations. The history of science shows us over and over again that a man "voyaging in strange seas of thought" may, if he be short of sight, find himself marooned on a desert island of fact, apparently cut off from the main continent of truth, when all the time the path is open were not his eyes holden so that he cannot see. This kind of error is best cured by the cultivation of the imagination which a study of poetry brings. Indeed, a wise age may put the poet's imagination to better use than we do, and it may be considered necessary to attach a poet to the permanent staff of every research laboratory. May not the man of imagination sometimes greatly assist the man of fact by finding short cuts to discovery of which the latter is not aware?

Apart from its utilitarian aspect the cultivation of poetry has, as Sir Humphry Rolleston points out, a great æsthetic value. The act of creation has a stimulant effect which no tonic in the *Pharmacopœia* can rival. If you can think at all no thoughts can delight you as your own. But the creative effort required for poetry is arduous, and perhaps the practitioner, tired from his busy day's routine, would be better advised to emulate, if he can, Sir Donald MacAlister by taking some fine thought already born in a foreign language and assisting at its palingenesis in his native tongue. This is still creation, though creation at second hand, for a really good translation must necessarily be creative. There is, too, in translation an element of adventure. The translator is a "bringer-over," or, in better parlance, a ferryman. Even if he founders with his cargo he will have perished in a good cause.

Certainly it is no vice to write poetry, though it may be one to publish it—an offence, however, easier to commit in times past. The day is no longer when an aspirant can circulate copies in MS. of his effusions to indiscreet friends in the secret hope that one of them will hand the script to the printer, and he be forced in mere self-defence to give to the world "a full and intended copy of that piece which was most imperfectly and surreptitiously printed before"—I am, etc.,

Sarbiton Oct 9th

E. W. ADAMS

MEDICAL WOMEN IN MIDDLE-ÆVAL TIMES

SIR.—The history of medicine has now become a serious discipline. It has its own scientific journals and its own methods of research. Its results are recognized by the general body of historians. Men of learning now look to those who write upon medical history for the same intellectual integrity as is exhibited in other departments of historical research. It has therefore become of importance for the advancement of learning, and is, moreover, not without some practical importance for the good name of the medical profession, that unguarded statements or untenable conclusions on medico-historical topics should not be carelessly thrown off. In a note in your issue of October 10th Dr. Redmond Roche writes as follows:

Under the Benedictine monks the first university of modern times came into existence at Salerno and there in the twelfth century women were admitted to the university and to the medical school, and the department for diseases of women was handed over to women professors. It has been said of the famous St. Hildegard (who died in 1179) that her writings disclose a better knowledge of science than any other writer man or woman, of her time. Reuss, editor of an edition of her works, says she knew many things unknown to the physicians of her time.

There is hardly a phrase in this paragraph that does not need revision. Salerno was not in our sense a university, but only a medical school. There is no evidence that this medical school was under or was founded by or was the work of Benedictines. There were no "professors" at Salerno in the twelfth century, and none of the teachers can be shown to have been women. The works ascribed to Salernitan women have been proved to be compiled from more ancient writings, and there is evidence that the

compilation of them was the work not of women but of men. There is no evidence for the existence at any time of a department for the diseases of women at Salerno. There is no evidence that women were "admitted" to the "university" in the twelfth century and very little that they were admitted at any other time.

St Hildegard did not die in 1179, but was alive and in fairly vigorous health at that date. The medical writings ascribed to her are but doubtfully hers. So far from disclosing a better knowledge of science than those of any writer of her time, they exhibit in fact backward material, and are far inferior to the translations being made from the Arabic by her contemporary Gerard of Cremona. The main interest to historians of the "scientific" works ascribed to Hildegard is precisely that they give a glimpse into the medicine of an earlier age than her own. In other words, their backwardness is their chief value. From the historian's point of view their chief drawback is, however, that they are not quite backward enough, for much that is in them can be traced to other sources.

Lastly, it would perhaps be needlessly harsh to recall the fact that the life of Saint Hildegard was not altogether truthful, were it not that the Roman Catholic Church, to which she adhered with greater vehemence than orthodoxy, has itself promulgated this conclusion.

If Dr Rocho seeks evidence for these revisions of opinion he will find it in the very extensive scientific literature on Salerno and on Hildegard that has appeared during the last quarter of a century. This literature will incidentally reveal to him the fact that the imperfect edition of the works of St Hildegard that appeared in 1882 was, with the exception of a single text, printed from earlier editions. Reuss was not its editor, though he did write an introduction to this single text.

It appears to me that the time has arrived when wild and undocumented statements concerning medieval medicine should cease to be bandied about. While such treatment of historical problems is liable to injure the cause of historical truth in general, it is certain to detract from the interest and value of medical history in particular.—I am etc.,

CHARLES SINGER

SURGICAL TREATMENT OF MITRAL STENOSIS

SIR,—We have to congratulate Mr. Soutter on successfully introducing a finger through the mitral valve of a living subject (BRITISH MEDICAL JOURNAL, October 3rd, p 603).

Examination of specimens at this hospital has shown us that in some young subjects mitral stenosis can be very extreme, the valve orifice barely admitting the tip of the little finger. Moreover, the fused cusps in these cases are often consolidated into a hard mass almost cartilaginous to the touch, the auricle is ballooned out, behind a ventricle starved of blood and withered in consequence.

Such cases are rare, but appear to us to be those calling for surgical relief of the obstruction. The tenacity of the valve mass necessitates the use of a cutting instrument.

In selecting cases of such high degree of mitral obstruction electro-cardiograms form an important part of the examination.

We would refer to some papers we published last year—the technique of mitralotomy in the *American Journal of Surgery* May 1924 and the relief of mitral obstruction, *New Zealand Medical Journal*, June, 1924.—We are, etc.,

J STICKLAND GOODALL

L C ROGERS, F R C S Edin

National Hospital for Diseases of the Heart London Oct 6th

SIR—I read with great interest Mr. Soutter's account of his operation on a case of rheumatic carditis (October 3rd p 603). I was not surprised to read that the mitral orifice was not found to be greatly stenosed, partly because of the physical signs he so well describes, and partly because, having observed some few children with progressive mitral stenosis over a number of years, I think it is seldom that a true cicatricial stenosis is established during childhood at all.

It is still quite insufficiently realized that the pre-

dominant feature, not only of rheumatic carditis in childhood, but also, in severe cases, of the heart failure which follows it, is infective (that is, rheumatic) myocarditis, and not any merely mechanical deficiency of the valves. The close relation that undoubtedly exists between mitral endocarditis and heart failure due to progressive myocarditis has not yet been fully worked out, but possibly in these severe stages of the disease the endocardial vegetations are the main source and the myocardium the main recipient of the toxins which result in failure of the heart.

One would suppose that in order to obtain a more suitable case for surgical treatment it would be better to look for a patient whose stenosed mitral valve was merely the result of a completely healed rheumatic lesion in bygone years, and it is only in later life that such are commonly found—I am etc.,

Bread St Oct 10th

MARTIN O RAVEN

"CONGRISS ASPHYXIA"

SIR,—Your General correspondent's account (September 26th, p 576) of the conditions under which the health organizations of the League of Nations work is deplorable but not in the least surprising. The International Congress of Child Welfare recently held in the same city would appear also not to have been above reproach in this respect. Dr Cecil Reddie, at the First Guildhall School Conference, 1912, mentioned having attended a lecture on school hygiene in Germany in a room where asphyxiation was imminent, and my experience when listening to the teaching of hygiene in Munich in January, 1914, was far from favourable. Nor shall I ever forget the expression of horror with which a Parisian manservant received the intimation of my intention to sleep with the windows wide open one cold Easter.

At the same time it is but fair to admit that the "furtive Anglo-Saxon" has not a good record in this matter. The atmosphere of the office of a well known health organization is such that I invariably beat a hasty retreat after a visit. An educationist member of the London County Council used to amuse himself by counting the number of open windows in Huxley Street, while one of the worst colds which I can recall was the sequel to a committee meeting held in the room of a specialist in tuberculosis. After a meeting in Hampstead in support of the garden city idea, when the air was thick enough to cut with a knife, a joint letter from the late Dr. Claude Fawcett and myself poking fun at the promoters for their inconsistency, and inviting officials of churches and clubs to apply to the local health society for assistance in improving their ventilation failed to evoke a single response. Presiding at a meeting at Essex Hall for the same object, an eminent medical man told his audience that as the result of the foul air they were breathing they would all be physically deteriorated the next day. From these illustrations, which might easily be multiplied, it must sorrowfully be admitted that as a people we are still far from having learned that the saying "cleanness is next to godliness" is applicable to air as well as to other things—I am, etc.,

CHARLES E HECHT,

Honorary Secretary Food Education Society

Weiminster SW Oct 10th

ADDITIONAL VOLUNTARY HOSPITAL ACCOMMODATION

SIR,—As Dr Ferdinand Rees (September 26th, p 585) does not answer my questions we must assume he thinks that this country is falling behind other countries in healthiness, that nothing will save its position except the immediate provision of 10,000 hospital beds, and that some measure of nationalization is necessary for the purpose. I gather that any other method than nationalization is something to be ashamed of, and that those who are not socialists are silly. The simplicity of this division of parties in the State takes my fancy greatly. As a member of the silly group I tried to point out that hospitals on the voluntary system have done magnificent work in the past, that there are signs that they may continue to meet the needs of the community in the future, that in times when economy is necessary even the superb clinics of

Switzerland should not make us in a hurry to embark on new ventures that may be very costly in their results, and that the proposals of the Voluntary Hospitals Commission have the same nationalistic foundation as those of the socialists. In addition to this the Commission's plan will have far-reaching effects on the medical profession, and it surprises me that so little interest seems to be taken in the matter by medical men.

I am now meditating on the curious political fact that whenever anything is thought to be wrong with any particular service or institution the cause is sought in some lack of representation. "The Hospitals Association," says Dr. Rees, "has no sense of citizenship, its policy is selfish and mediocritous." The reason seems to be that neither he nor I is represented on that body—I am, etc.

Felstead Sept 28th

CHARLES BUTLER

LEEDS UNIVERSITY AND THE MEDICAL PROFESSION

Sir,—The old Leeds Medical School is approaching its century of existence, in which a steady progress of development has been marked from time to time by substantial additions to its accommodation. Since 1893, the date of completion of the present buildings, there have been no structural alterations commensurate with the progress of physiology and pathology, the closer co-operation of laboratory and clinical departments, and the increase of the general and special hospitals and the public health organizations, which all add to the obligations and opportunities of service of the Medical School.

The support given by the medical profession to the school in times past was both generous and important. The example of former days is our justification, at this critical time of need for expansion, for making a special appeal on behalf of the school.

The University is fully aware of the value of the Leeds Medical School, and desires very earnestly to promote the usefulness of this Faculty with no less care and energy than it devotes to the development of the Faculties of Arts, Science, and Technology. For this reason the urgent needs of the Faculty of Medicine have been acknowledged by the University, and in making its general appeal to Yorkshire it feels that the greatest assistance may be derived from the spirit of the profession which by its own endeavours raised a medical school from casual meetings in the back room of the old dispensary to a position of respect and eminence in the medical world.

At the present time there is neither accommodation nor equipment to permit the University to set men on to meet the demands for investigation and service required by the community. Even the present staff, honours and otherwise, are prevented from giving their energies and enthusiasm to current problems by this lack of facilities. It is earnestly hoped that the members of the profession will give all the assistance in their power towards the object of the University, which is to make its medical departments capable of acting as a fruitful and useful centre of research and information and equal to their obligations to our large industrial population—We are, etc.,

DEVONSHIRE,

Chancellor

J. KAY JAMESON,

Dean of the Faculty of Medicine

The University, Leeds
Oct 12th

THE SUPPLY OF ARTIFICIAL LIMBS

Sir,—Our attention has been drawn to the article in your issue of October 3rd (p. 619), and to the suggestion therein that the contract placed by the Ministry of Pensions with my company and Messrs Hanger may "produce a state of things in which further possible improvements in details and in types will be discouraged."

The Ministry of Pensions made it a *sine qua non* in giving the contract to our respective firms that a clause should be inserted fully covering the Ministry and pensioners in this respect. In consequence, the Ministry of Pensions has amplified its demands.

It is necessary to point out that this contract only applies to light metal limbs, of which ourselves and the other con-

tracting firm have probably supplied nearly 90 per cent of the total number supplied to date—I am, etc., for and on behalf of Pedestrian, Ltd.,

London W 1 Oct 13th

T. BRYANT SMITH,
Director

Obituary

R. C. CHICKEN, F.R.C.S.,

Consulting Surgeon Nottingham General Hospital

MR. RUFERT CICIL CHICKEN, whose death occurred on October 3rd, was born in Nottingham about 1850. After studying at Guy's Hospital, he obtained the diplomas of M.R.C.S. in 1872, L.R.C.P. in 1873, F.R.C.S. Eng. in 1875, and L.S.A. in 1877. He occupied the posts of house-surgeon and obstetric assistant at Guy's, registrar at the Plymouth Hospital, and professor of anatomy at the Royal College of Surgeons. On returning to his native town he became partner with Mr. Wychin, whose death in the early eighties left Chicken in sole charge of a large mixed general practice. This was a great handicap on a man who by previous training and natural aptitude was fitted to be a surgeon. Nevertheless, he found many opportunities of practising the art he loved, both among his own patients and those of his neighbouring colleagues who sought his opinion. Thus he was able to maintain his operative skill and keep in touch with the progress of surgery.

His long-cherished hope of obtaining a hospital appointment came to fruition in October, 1891, when he was elected to the staff of the Nottingham General Hospital. With characteristic generosity he remarked "Now I shall be able to help my friends." The next ten or fifteen years of his life were a period of great surgical activity, both public and private. Elected president of the Nottingham Medical-Chirurgical Society in 1892 he gave as his address "The treatment of hernia." As illustrating the wide range of his surgical interests, the following titles of papers, etc., contributed to the same society may be mentioned: "The surgical treatment of tumours of the thyroid" (1886, 1894), "Cystic tumour of testis" (1890), "Wolff's operation for loose fibro cartilage," "Trigeminal neuralgia, excision of a portion of the lingual nerve," "Trigeminal neuralgia, a modification of the operation for resection of the second division" (1892), "Patient after tiephoning for abnormal sensations in right thumb," "Lupus erythematosus," "Resection of intestine for intussusception" (1894), "Some operations in the hepatic region," "Indications for, and results of, removal of the uterine appendages" (1896-97), "Operation for perforated gastric ulcer" (patient shown, 1897), "Some operations on the digestive organs" (1897), "Excision of rectum for carcinoma," "Gastrotomy for oesophageal cancer" (1898), "Operation for gangrene of lung" (patient shown), "Abnormal semi-lunar cartilages," "Hydrocele," "Tubal abortion" (1899), "Ligature of common carotid (patient shown, 1900), "The bowels of appendicitis," "Elephantiasis of scrotum," "Radiograph of myositis ossificans" (1901), "Operation for musculo-spiral paralysis" (two patients shown), "Prostatectomy by Meyer's method" (1902). In spite of ill health, which clouded the latter years of his life in Nottingham, his surgical activity continued unabated and the above list might have been greatly extended. His long and painful disabilities with uncomplaining fortitude and quiet resignation. On his retirement from the hospital staff and from practice in December, 1907, he was appointed consulting surgeon to the hospital for life.

He was a sound and careful surgeon, well abreast of the knowledge and technique of his day. He did not adopt new methods without careful consideration and conviction of their utility. If he pinned his faith to sponges after the era of swabs had come in, he could claim with justice that his wounds remained free from sepsis. If he refused to treat his fractures along lines which at the time were new and revolutionary, he lived to see the day when some leading surgeons were advocating a return to older methods. In addition to his professional interest he was a man of wide reading and culture. A collector of old oak and silver, he was a student of local history and archaeology. He compiled and published a valuable *Index to Deering's History*

of Nottingham (1899) He also wrote a booklet on *Excavations at the Nottingham General Hospital during the Building of the New Wing* (1899) He had to fight for his position, and reached the goal in spite of difficulties. He fought without enmity, and did not cherish any aftermath of bitterness. He was of a kind and generous disposition, as many of his colleagues can testify, to whom he freely gave his time and skill in their sicknesses. To one of these who thanked him for his help he said, "Think of the pleasure I have had in doing it."

After leaving Nottingham Mr. Chicken acted as ship surgeon for a year or more, in the hope of regaining his health. During the war he held the post of surgeon to the Whipp's Cross War Hospital, Leytonstone. He also resided at Hemel Hempstead and Chichester. His last home was at Sandgate, Folkestone. He leaves a widow, one son, and two daughters.

C F SONNTAG, M.D. EDIN.

Professor, Zoological Society of London, formerly Hydrologist, Military Orthopaedic Hospital, Shepherd's Bush.

DR. CHARLES FREDERICK SONNTAG, Professor to the Zoological Society of London, died suddenly on October 10th at his residence in Belsize Park Gardens. He had contracted phthisis while on active service during the war, and his death, at the early age of 37, was attributable to this.

He was a native of Glasgow, and received his medical education at Edinburgh University, where he graduated M.B., Ch.B. in 1910, and proceeded M.D. with honours in 1912. Soon after the outbreak of war he joined the Royal Army Medical Corps and saw active service as regimental medical officer in several units of the Salonika Expeditionary Force. In 1916 he was invalided home, and the end of the war saw him in charge of the hydrotherapy department in the Military Orthopaedic Hospital, Shepherd's Bush. Although in the years after the war he became engrossed in anatomical research, he still continued his interest in hydrotherapy, and for some time acted as honorary secretary of the Balneological Section of the Royal Society of Medicine.

Sonntag even when at school had made a study of zoology and comparative anatomy, and was always insistent on the value of this training in his medical and surgical work. While engaged in his duties at Shepherd's Bush he attracted the notice of Professor F. Wood Jones, who, quick to notice Sonntag's abilities as a comparative anatomist, recommended him for the post of Professor to the Zoological Society, to which position he was elected by the Council in August, 1919. In spite of his failing health he threw himself into his new work with great ardour and enthusiasm, and the thirty papers on vertebrate anatomy which he contributed to the *Proceedings* of the society in the ensuing six years bear witness to his boundless energy. Much of his work was on the anatomy and physiology of the anthropoid apes, and in addition to several papers on this subject, in 1924 he published a treatise on the morphology and evolution of the apes and man. Besides his work at the Professorium he held the post of demonstrator in anatomy at University College.

He will be mourned by a large circle of friends, who looked upon him with that respect which is earned by honest hard work, and will remember him for his ready wit and cheery optimism in the face of much physical suffering. The funeral took place at Fortune Green Cemetery, Hampstead, on October 13th. Among those present were Sir Arthur Keith, Professor Elliot Smith, Professor J. P. Hill, Dr. P. Chalmers Mitchell, and many other scientific friends and colleagues.

G. M. V.

THE LATE DR. W. MORRISTON DAVIES

DR. J. B. PYLE (Loughborough) writes: "With regret I saw in the *Journal* of October 3rd (p. 629) an obituary notice of Dr. Morriston Davies. My chief recollections of him date back about fifty years, when he was the junior partner in the firm of Foster, Lucas and Davies. I was house-surgeon at Huntingdon County Hospital, and repeatedly I went with Dr. Davies to give an anæsthetic or to assist at an operation. Dr. Davies was one of Lord

Lister's early pupils, and introduced antiseptic surgery at Huntingdon with its primary technique. I remember one case of breast amputation in which hæmorrhage was kept up by the warm carbolic spray and ceased on its discontinuance. My memories of Dr. Davies are all happy ones, recalling to my mind youthful friendliness and enthusiasm."

Professor O. KUKULA, director of the first surgical clinic, and Rector Magnificus of the University of Prague, has recently died at the age of 58. He was the author of an important monograph on the pathology and treatment of appendicitis.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE

THE following candidates have been approved at the examinations indicated:

D.P.H. (BOTH PARTS)—*Old Regulations*: J. R. Hayman, J. A. G. Kedde, W. B. Stott. *New Regulations*: A. N. Fergus, Mary A. Hene, R. A. Mansell, C. F. Pedley, C. J. Stocker, F. C. Tibbs, M. E. Yee. DIPLOMA IN HYGIENE—A. R. Hassan, L. Shehata.

* Distinguished in Part I. † Distinguished in Part II.

UNIVERSITY OF LONDON

At the matriculation examination of the University of London held in September there were 42 successful candidates in the first division and 411 in the second division, in addition, 57 took the supplementary certificate for Latin.

UNIVERSITY OF ABERDEEN

At the opening of the winter session in the Faculty of Medicine of the University of Aberdeen on October 6th the Principal of the University, Sir George Adam Smith, welcomed informally Dr. Alexander Low, the newly appointed professor of anatomy in succession to Professor R. W. Reid, who has retired after thirty-six years' tenure of the chair. Tributes to Professor Reid and Professor Low were paid by Professor J. A. MacWilliam in his opening address to the class in physiology and by Professor Ashley Mackintosh in opening the class in medicine.

UNIVERSITY OF ST. ANDREWS

At the graduation ceremony held at St. Andrews University on October 9th Principal Sir James Irvine inducted Mr. David Dow, M.B., Ch.B., D.P.H., to the chair of anatomy in University College Dundee. There was a large attendance of students. In welcoming Professor Dow the Principal said he had fitted himself for promotion by a diversity of experience gained in a wider atmosphere than that of the classroom. For ten years he had combined his university studies with the practice of his profession in Fife and had found time to carry out researches.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

THE following candidates have been approved at the examinations indicated:

FINAL M.B.—Part I: S. Behr, Wilfreda, D. C. T. Pigott, W. F. La. R. M. Moore, G. V. Smith, P. M. Garry, T. F. Woods, L. R. Macfarlane, C. L. Day, N. Bernstein, D. M. Carson, G. M. Donald, A. C. Charles, J. A. FitzGerald. In completion: Kathleen E. Byrne, Evelyn D. Connolly, D. Blewitt. DIPLOMA IN GYNÆCOLOGY AND OBSTETRICS—J. Rego, Amy B. B. A. Perriton.

* Passed on high marks.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Stratfield Research Scholarship

MR. NORMAN LESLIE CAPESEN, F.R.C.S., has been appointed Stratfield Scholar. The subject of his research will be "The comparative anatomy and function of the prostate gland." His research will be carried out at St. Bartholomew's Hospital and the Zoological Society.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A QUARTERLY Council meeting was held on October 8th when the President, Sir John Bland Sutton, Bt., was in the chair. Diplomas of Membership were granted to eight candidates.

The Gilbert Plane Medal

The Sir Gilbert Plane medal was awarded to the following medical officer of the Royal Navy in respect of the Promotional Examination 1925: Surgeon Lieutenant Commander Lionel Frederick Struonell, M.B., B.S.

Lectures

The Bradshaw Lecture on Gas Resonance was delivered by Mr. James Sherren on Wednesday, November 11th, at 5 p.m. and the Thomas V. medieval conception of the anatomy and nervous system by Professor William on November 18th, at 5 p.m.

Medical News.

A COURSE of four lectures on general anaesthesia, arranged by the Dental Board of the United Kingdom, will be given during the present winter session. The first lecture, entitled "Respiration in anaesthesia," and the second, on the absorption and elimination of volatile substances in the lungs, will be delivered by Professor Yandell Henderson of Yale University. The third lecture, on the circulatory changes in anaesthesia and the use of oxygen, will be given by Professor Leonard Hill, M.B., F.R.S., and the fourth by Professor Noel Paton, M.D., F.R.S., on the metabolic changes in chloroform poisoning. The lectures will be delivered in London at the Royal Society of Medicine, 1, Wimpole Street, on October 22nd, 23rd, and 30th, 1925, and January 11th, 1926, at 8.30 p.m., in Manchester, in the Medical School, University Buildings, on October 26th and 27th and November 3rd, 1925, and January 13th, 1926, and in Edinburgh, in the University, on October 29th and 30th and November 5th, 1925, and January 15th, 1926, at 5 p.m. The course is intended primarily for dentists and medical practitioners, tickets of admission are not required.

The Fellowship of Medicine announces that Dr Marcus Paterson will give a lecture on the diagnosis of pulmonary tuberculosis on October 19th, at 5.30 p.m., in the lecture hall of the Medical Society of London, 11, Chandos Street, W.1, members of the medical profession will be welcome. The Chelsea Hospital will hold a three weeks' course from November 2nd, consisting of demonstrations, operations, and lectures by members of the staff. Throughout November the London Lock Hospital has arranged a comprehensive course in venereal diseases. The Royal Waterloo Hospital will give a course from November 23rd to December 12th in the study of diseases of children and women from all aspects. From November 3rd to November 28th Dr Porter Phillips and Dr Thomas Beaton will give lecture demonstrations twice weekly on psychological medicine. An evening course for general practitioners has been arranged at the London Temperance Hospital from November 1st to 13th. There will be a course in diseases of the chest, heart, and lungs at the Victoria Park Hospital from November 9th to 21st. Copies of any syllabus and of the general programme may be obtained from the Secretary, 1, Wimpole Street, W.1.

DR PATRICK WATSON WILLIAMS will deliver the Semon Lecture in the Robert Barnes Hall of the Royal Society of Medicine on Thursday, November 5th, at 5 p.m.

THE Devon and Exeter Medical-Chirurgical Society will hold its first meeting on Friday, October 23rd. An address will be given by Sir St. Clair Thomson on the surgical anatomy of the nose and accessory sinuses.

AT the next meeting of the Medical Officers of Schools Association, which will take place at 11, Chandos Street, W.1, on Friday, November 6th, at 4.45 p.m., Dr A. I. Slimey, medical officer to Rugby School, will read a paper on the prophylaxis of common colds.

THE annual dinner of the University of Bristol Association of Alumni (London Branch) will be held at 7.45 p.m. on November 6th at Pagani's Restaurant, Great Portland Street, W. Viscount Haldane will preside and Professor Lloyd Morgan will be the guest of the evening. The charge for the dinner is 9s. exclusive of wine. Further particulars can be obtained from Dr Elizabeth Casson, Holloway Sanatorium, Virginia Water.

FOLLOWING the opening lecture of the winter session at the Central London Throat, Nose, and Ear Hospital by Dr. William Hill on October 6th, the annual dinner of the medical staff was held at the Trocadero Restaurant the next evening, with Mr Harold Kisch in the chair. A total of fifty-two were present, and among the guests were the lecturer, Dr. William Hill, Sir St. Clair Thomson, President of the Royal Society of Medicine, Sir W. Aitken, President of the Fellowship of Medicine, Sir Thomas Horder, Dr W. H. Kelton, Mr Herbert Paterson, Mr Herbert Lilley, Mr C. J. Badgerov, Mr I. B. Layton, Dr Watson Williams, Dr J. H. Chaldecott, and the chairman of the committee of management of the hospital.

THE annual dinner of the Manchester Medical School will be held in the Grand Hotel Manchester on Thursday, November 19th, with Mr C. Roberts in the chair.

THE first dinner meeting of the Hunterian Society of London will be held at Simpson's Restaurant Bird in Hand Court 77, Poultry, Cheapside, on Monday, October 19th, at 7.30 p.m. After dinner the presidential address, on light, will be given by Dr I. Howard Humphries.

DR JEAN CHARCOT the well-known explorer, and Dr Schleich, professor of otorhino-laryngology, in the Paris Faculty of Medicine have been nominated Commanders of the Legion of Honour.

THE annual sermon of the Royal College of Physicians of London, recently established by the Charity Commissioners under the Sadler Trust, will be preached at the Church of St. Mary le Bow on Monday, October 19th, at 12 o'clock.

THE freedom of the borough of Abergavenny has been conferred on Dr. William Dyma Steel, who recently retired from the office of medical officer of health for the borough after forty-two years' service. Dr. Steel was formerly President of the South Wales and Monmouthshire Branch of the British Medical Association and Representative and Chairman of the Monmouthshire Division.

DR J. CROSSIE DIXON of Banstead has accepted the unanimous invitation of the Barnes and Uxbridge Council to become a member of the borough for the coming year.

DR FRANKS MARRIOTT of Alfreton has been added to the Commission of the Peace for the county of Derby.

DR. HUBERT V. LEIGH, on the occasion of his leaving Treherius, has received from his friends and patients an illuminated address, and Mrs. Leigh a silver tea and coffee service.

AT the annual meeting of the Royal Academy of Medicine in Ireland held on October 9th the following officers were elected: President, Sir James Craig; General Secretary, Dr. T. P. C. Kirkpatrick; Secretary for Foreign Correspondence, Dr. L. L. Cassidy; Presidents of Sections (Medicine) Dr. F. C. Purser, (Pathology) Dr. Joseph W. Bigger, (Surgery) Mr. R. C. B. Vansell, (Anatomy and Physiology) Dr. C. M. West, (Obstetrics) Dr. D. G. Madill, (State Medicine) Dr. V. M. Syngé.

A STATUE to Pasteur was unveiled recently at Rio de Janeiro.

AN anonymous donor has given £50,000 to the London Hospital. The gift, which has been made through Viscount Knutsford, the chairman of the hospital, is to be devoted chiefly to research work, and special attention is to be given to rheumatic diseases and troubles arising therefrom.

DR HARVEY CUSHING, Moseley Professor of Surgery, Harvard University, and surgeon in chief at the Peter Bent Brigham Hospital, Boston, Massachusetts, was awarded the Cameron prize of the University of Edinburgh last year. He will deliver three lectures in the University this month, the first on Monday next, on the circulation of the cerebrospinal fluid, the second on Tuesday, on the pituitary gland, and the third on Thursday, October 22nd, on brain tumours. The lectures will begin at 4 p.m. on each day. Students and graduates in medicine are invited to attend.

THE King has granted to Dr. Percy G. S. Williams, Principal Medical Officer of Health, Cairo City, permission to wear the insignia of the third class of the Order of the Nile, conferred upon him by the King of Egypt in recognition of valuable services rendered.

THE thirty-second congress of the Italian Society of Surgery will be held at Rome from October 25th to 28th, when the following subjects will be discussed: (1) Treatment of Graves's disease (conjoint meeting with the Italian Society of Internal Medicine) introduced by Professor P. Fiori; (2) Intestinal obstruction (exclusive of strangulated hernia), introduced by Professors Gresle, Margarucci, and Ugo Stoppato.

A STAINED glass window erected to the memory of the late Dr. William Hurrell Mason was unveiled recently at St. Peter's Church, Hunlet Moor, Leeds, by the Vicar of Leeds, the subject of the window is "The Beloved Physician."

SIR WILLIAM D. NICHOLLS has given the mansion Ty To Maen at St. Mellons, together with its twenty acres of parkland, to the Cardiff Royal Infirmary for use as a convalescent home. Ty To Maen was the former residence of Mr J. C. Gould, shipowner and is situated in delightful country overlooking the Bristol Channel. It is expected that with but slight alterations the house will provide accommodation for some sixty or sixty-five beds.

THE September issue of *Medical Science Abstracts and Reviews* completes Volume XII and is the last of the series, the Medical Research Council having resolved to discontinue its publication.

THE annual report for 1924-25 of the Committee for Scientific and Industrial Research has been issued (H.M. Stationery Office, price 3s.). We hope to deal with this report later, but meanwhile may note that the expenditure amounted to £173,455, and that of this £50,000 was provided by fees for tests and for special investigations for outside firms or by contributions from co-operating bodies and £30,000 from repayments from the Service departments for work undertaken directly for them.

THE eighth Sicilian Medical Congress, which was to have been held this month, has been postponed until next April.

THE Wellcome Historical Medical Museum will be closed for cleaning and structural alterations from October 19th until November 30th.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the British Medical Journal must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the British Medical Journal are *MUSEUM 3861, 3862, 3863, and 3864* (internal exchange four lines).

The TELEGRAPHIC ADDRESSES are

EDITOR of the BRITISH MEDICAL JOURNAL, *Antiology Westcent, London*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent London*

MEDICAL SECRETARY *Medisecra Westcent London*

The address of the Irish Office of the British Medical Association is 16 South Frederick Street Dublin (telegrams *Beacillus Dublin*, telephone 4737 Dublin), and of the Scottish Office 6 Drumsheugh Gardens, Edinburgh (telegrams *Associate, Edinburgh*, telephone 4361 Central).

QUERIES AND ANSWERS

"G H L" writes: I have as patient an elderly man suffering from chronic osteoarthritis of the left hip. He complains of a feeling of stickiness all over his body, but particularly over the affected hip. This is not imaginary, as the affected parts are distinctly sticky to the touch. Can any explanation of this condition be given?

TREATMENT OF NAEVUS

F E C" asks if trichloroacetic acid in crystalline form is a satisfactory treatment for a large superficial naevus on the abdomen of a young baby, and whether the application is painful. The child is in the country and it would be difficult to arrange for treatment with CO₂ snow or electrolysis.

ANOSMIA AFTER CORYZA

G S A" asks for suggestions for the treatment of the following case. A man, aged 55, who usually enjoys good health, suffered from an attack of coryza in February 1925. The temperature was 100° for two days, but he did not lie up, he lost his taste and smell, but thought nothing of this expecting it to return, but it has not, he has tasted nothing since. The sense of smell is present to a certain extent but perverted: food, coffee, turpentine ammonia, etc., all have the same musty order. What is the prognosis in these cases?

*. Anosmia is generally recognized as a widespread early symptom of influenza, and Smith Ely Jelliffe and H Lawson White (*Influenza* Essays by several authors edited by T G Crookshank) state that it may persist for a long time. White adds that perversion of smell is also a not infrequent complication, and regards the condition as a true neuritis of the olfactory nerve. Having encountered a case in which it persisted for twenty years, he recommends a very guarded prognosis. In the *Index of Treatment* by Hutchinson and Sherren it is stated that the most hopeful treatment of influenzal anosmia is the internal administration of large doses of strychnine and phosphorus, arsenic also may be tried.

INCOME TAX

Motor Car Expenses of Salaried Officer

W S G" receives a salary from a local authority, and also a mileage allowance, which he states covers running but not overhead costs. He has recently spent money on replacing his car. Is this allowable?

*. Our correspondent is entitled to deduct sums expended wholly exclusively, and necessarily in the performance of the duties of his office. If it is necessary for him to use a car for travelling on his professional work—as apparently it is—he can deduct the excess of the actual expenditure (excluding capital outlay) over the mileage allowance received. The matter is, however, by no means free from difficulty. In the first place, the authorities will probably expect him to substantiate beyond doubt his view of the allowance—that is that the local authority did not fix it on the assumption that it would cover overhead charges and secondly the renewal cost of a vehicle is strictly referable to its life in use and 'W S G' must be prepared to face a claim to set off any excess of allowance over running cost during the use of his recent car from the loss on the running of the car in the year in which the special expenditure was incurred.

LETTERS, NOTES, ETC

MEDICAL GOLF

THE Medical Golfing Society held its annual autumn meeting on October 10th and 11th at Dowl, by kind permission of the Royal Craguon Ports Club. The course was in excellent condition and the weather glorious. The results of the competitions were

Singles v Bogey—L W Bathurst 3 ap. *Second prize* W H

S. 9
11.

THE autumn meeting of the Shropshire Medical Golf Association was held on October 11th on the Wrekin golf course by kind permission of the committee. There was some fog in the morning but after 11 o'clock the weather was delightful and the course in

The Shropps owl (18 holes, medal play) scores were
was won by D

T R Elliott	82 - 9 = 73
A D Haydon	84 - 10 = 74
W B A Lewis	94 - 18 = 76
I B Richardson	89 - 11 = 78
J Glyn Pigott	98 - 18 = 80
H G Beckett	93 - 13 = 80

The foursomes v bogey were won by Drs Richardson and Beckett Drs Ireland and Higginson tying with Drs Wheatley and Elliott for second place.

Dr I B Richardson was elected captain for the ensuing year and Dr T R Elliott honorary secretary. A very hearty vote of thanks was passed to the returning captain Dr Higginson for the great interest he had taken in the association during his year of office. It was decided to hold the next meeting at Church Stretton towards the end of May, 1926.

COD LIVER OIL AND ULTRA VIOLET LIGHT

It has been suggested that the oxidation of cod liver oil causes it to emit ultra violet rays. This however is denied by F Daniels and R J Fosbinder who contribute to *Science* for September 18th 1925 (p 286), a brief account of experiments which they have made in the laboratory of physical chemistry at the University of Wisconsin. After bubbling oxygen through cod liver oil in a quartz cell for ten days, no darkening of a photographic film was discernible, nor was any trace of a photographic effect produced by heating cod liver oil to 100° C while oxygen was passed through it for three days. The oxidation however altered the character of the oil, as was shown by a change in its iodine number. A control experiment working properly and that the

lution of oxygen as the cure of the oxidized cod liver oil was on oxidized cod liver oil was were taken to expel dissolved unfortunate that the previous tinted ultra violet rays should have led to widespread speculation concerning the mechanism of the cure of rickets.

POETRY AND PHYSIC

"R C B" sends the following verses under the heading *Po eleganti Medico, malus Poeta*, a phrase assigned by Erasmus to Plutarch.

Though Providence meant to have us content
Some folks are well off and don't know it
So heed ere too late that victim of fate
The doctor who would be a poet
Once bright and alert and physico-expert
See him now count his feet in his walk
Or stopped in the street a patient's reet
Hear him stammer to rhyme in his alk
His patient in fear he'd comfort and cheer
By questions all cast into metro
Prescriptions he'd frame with a metrical aim,
He thought more effective and neater
Nocturnes he'd indite in the hours of the night
The mother with chloroform soothing
The baby newborn at break of the morn
He'd hail with an ode to its toothings
He failed for alas! this will come to pass
His life synopated until
In the season of cheer at the end of the year
He starved lacking rhymes for his bill

ROAD PLAYS

THE Dunlop Rubber Company Ltd has now issued the fourth and fifth volumes in its series of pictorial road plays *O, the Road*. The publishers are Ed J Bnrow and Co Ltd Chell a ham, and the price is 6d each. The fourth volume conducts the traveller to Holyhead, the other round the English lakes to Glasgow.

VACANCIES

NOTIFICATIONS of offices vacant in universities medical colleges and of vacant resident and other appointments at hospitals will be found at pages 37 39 40 41 44, and 45 of our advertisement columns and advertisements as to partnerships assistantships and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at pages 135 and 136.

The Harveian Oration

OR

HEREDITY IN RELATION TO
MENTAL DISEASEDELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS
ON LONDON ON OCTOBER 19TH, 1925,

BY

SIR FREDERICK MOTT, K B I , M D , LL D ,
FRCP FRCS

[THE ORATOR began by referring to Harvey's *de Generatione Animalium*, which, he said, stood in a place of equal honour by the side of his doctrine of the circulation of the blood. He mentioned the Harveian Orations by the late Dr Ormerod (1908), by Sir Bryan Donkin (1910), and by Dr Herbert Spencer (1921), who had dealt with various aspects of this book of Harvey's. Sir Frederick Mott then gave a sketch of the growth of knowledge with regard to Harvey's dictum, "*Omne inum ex ovo*," and continued as follows.]

Omne inum ex ovo—the life of the individual begins from the moment of penetration of the spermatozoon into the egg when the conjugation of the male and female gametes occurs. The spermatozoon provides one half of the nuclear matter (chromosomes), the ovum provides the other half. The spermatozoon carries into the ovum the centrosome, and in the process of repetitive cell division which follows it acts in such a way that every cell of the body contains an equal amount of nuclear material derived from each parent in respect to the hereditary material of the species. The discovery of the special sex chromosome in spermatozooids of insects shows that two sets of spermatozooids may be produced: those with an odd sex chromosome which gives males, those with a pair of sex chromosomes which give females, or, as occurs in some insects, one chromosome is small, that of the future male, and one large, that of the future female. Racial characters may not be equal in the amounts of nuclear matter in the form of chromosomes or genes derived from each parental stock, and still less those due to familial inbreeding, to which the greater number of mutations in man may be ascribed. Although there is disjunction of the paternal and maternal chromosomes, yet if these chromosomes are constituted by a series of genes or hereditary factors arranged in linear order, it follows that the crossing over of blocks of these genes may lead to fusion or transference and replacement of blocks of genes representing respectively maternal or paternal unit characters. Moreover, this crossing over of groups of genes in argument offers a germinal mechanistic explanation of facts observed by Galton in *Natural Inheritance*, where he says:

We appear severally to be built up of a vast host of minute particles of whose nature we know nothing or any one of which may be derived from any one progenitor but are usually transmitted in aggregate considerable groups being derived from the same progenitor. In the process of transmission by inheritance elements derived from the same race are apt to appear in large groups just as if they had clung together in the pre-embryonic stage as perhaps they did.

One of the most valuable contributions to our knowledge of character and temper depending upon an "inborn disposition impressed by Nature" was Galton's inquiry into the history of similar and dissimilar twins, it showed that temper and the raw material of character are inherited, so he found that identical twins brought up under a different environment remained temperamentally the same and of the same disposition, whereas dissimilar twins brought up in the same environment remained temperamentally different. We can only explain this on a chromosomal mechanistic basis by the supposition that in identical twins two male gametes conjugate with two female gametes in one ovum. But this inquiry of Galton's shows how much conduct and character depend upon inheritance. Moreover, an inquiry which I instituted and which was carried out for me by Miss Agnes Kelley in the parish of Bethnal Green showed that life tends to beget life.

This inquiry was made with the object of comparing the heredity and social conditions of a certain number of insane, mentally defective and normal persons. Sixty cases were taken in each group. The first group was of adult patients in the London County Council asylums, the second of high grade mental defectives the third of normal children from the elementary schools. The last two groups were at schools in different districts of Bethnal Green. Every care was taken to make as full and complete a family and social history as possible and pedigree charts were constructed. The report was published in Part II Annual Report of the Board of Control 1935 and the following is a very brief summary of the results of this inquiry.

Insanity was very much more prevalent in the pedigrees of insane persons than in those of mental defectives—namely, in the proportion of 50 per cent. as against 25 per cent. of the defective cases. Conversely mental deficiency was more apparent than insanity in the family histories of the defective children, while the charts of the normal school children only showed insanity and mental deficiency in a very small percentage of cases.

Good trades and high wages were rare in the mentally defective group. Though there were a few exceptions, the general type of employment was poor and 75 per cent. of the fathers were casuals and unskilled workers.

There was a corresponding dead level of poverty in the home conditions of these cases and the incapable mother was very conspicuous in this group. In few of the asylum cases and among still fewer of the mental defectives could the home conditions be described as good, while one third of the homes in each of the two groups were classed as homes in which the food was quite inadequate, the clothing very poor and bare necessities were lacking. The normal group showed a decided improvement in industrial conditions and in the care of home and children and there were very few cases of intense poverty or neglect. There was further a very striking contrast in the dependence on parish and charitable assistance among the families of the normal group on the one hand and of the insane and mentally defective groups on the other. The normals not only applied less often to the parish but they were also less well known to charitable agencies.

But mental deficiency exists in all grades of society, and in a number of cases heredity does not explain how it is that a child is born an idiot or imbecile and the brain is arrested in its development.

The foundations of moral and intellectual characters are inborn, but the influence of education, example, and environment generally is much more potent for good or evil than in the case of physical characters. Unfortunately the high grade imbecile and moral imbecile are fertile, and as they have only a narrow margin of highest control they readily yield to the impulses of the passions and animal instincts, or are unable to resist temptation when opportunity offers. Speaking of this raw material of character, which in a great many instances results from a failure of the latent potentialities of the fertilized ovum, Sir Thomas Browne (whose birthday it is to-day) clearly recognized the inborn disposition when he said: "Bless not thyself that thou wert born in Athens, but among thy multiplied acknowledgements, lift up one hand to heaven that thou wert born of honest parents, that modesty, veracity, and humility live in the same egg and come into the world with thee."

From time immemorial the influence of the sexual function on physical structure, character and conduct has been known but it is only within recent times that experimental investigations and clinico-anatomical observations have shown that this influence is dependent upon an internal secretion of an interstitial gland of the testis and ovary respectively which can function independently of the genetic structure. The testis secretes a hormone which determines prior to birth, the physical and mental sexual characters and at puberty the secondary sexual characters. The reproductive organs are functionally correlated with the endocrine system of glands, especially the cortex, adrenals, the pituitary, and the thyroid. As the sex instinct gradually matures a progressive mental and bodily evolution takes place in the male and female, in accordance, not only with the innate dispositions due to sex, race and familial ancestry, but with the evolution of character due to good or bad habit formations. Habits acquired in early life, although not germinal and transmissible, nevertheless form such stable organized reflex patterns in the nervous system as to be capable of profoundly influencing such inborn dispositions as the moral sense, the self-regarding sentiments, the emotions and passions, and their proper control. At the adolescent period a new great vital urge, stronger even than self-preservation energizes all the organs and tissues of the body, especially the nervous system, for the supreme biological end of reproduction and preservation of the species.

I will now give a short account of my own investigations regarding the interstitial cells in man and their functions. Examination of the testis of a full-term twin foetus showed tubules containing embryonic spermatogenic cells, between them, lying in loose connective tissue, were seen abundant polygonal cells with a round nucleus lying in an eosin-stained cytoplasm. Many of the cells had the appearance of young cells. There was plenty of evidence of nuclear mitosis, and I came to the conclusion that numbers of the cells had attained maturity and were on the way to a regressive atrophy, leaving only the nuclei. These cells contain a lipochrome substance and lipid granules. I found that about the fourth month the seminiferous tubules are twice the size of those at birth, instead of being separated by loose connective tissue containing abundant Leydig cells, they are closely approximated, the Leydig cells have almost disappeared, and there are no lipid granules visible. At the eleventh year I observed very little change in the size of the tubules and the interstitial cells are only discernible by examination with an oil immersion lens. Little or no interstitial lipid is seen. There are commencing manifestations of nuclear activity and karyokinetic figures, but no spermatids or spermatozoa. The Leydig cells do not reappear until puberty, when the generative function commences, and the sexual hormone from the interstitial cells begins again to pass into the circulation and determine the bodily and mental secondary sexual characters.

Seeing that the male sexual hormones are active for probably more than six months in pre-natal and post-natal periods, it follows that this influence must have been operating on all the somatic cells, including the nervous system, during all that time. If there be an elective storage of the sexual hormone in the nervous system, as Steinach's experiments indicate, then a masculine behaviourist tendency may thus early be engraven upon the nervous system. Moreover, by the sensitizing influence of the testicular hormone, the primary male characters are in this early stage made dominant in all the bisexual somatic cells. The belief in the occurrence of male sex-dominance at an earlier age than the existence of a secretion of the female sex hormone has received fresh support in the very interesting solution of the riddle of the "free martin" by Lillie. He reports a case in which the female characters of a female twin calf were more or less completely suppressed and certain male structures developed as a result of anastomosis of the placental blood vessels with those of the associated male twin calf. This can only be explained by the influence of a soluble and diffusible hormone derived from the male and carried to the female by the circulating blood.

There can be no development of sex characters without all the other organs of internal secretion participating, all of the ductless glands, and especially the thyroid, the pituitary, and the adrenal, are influenced by the internal secretion of the sexual glands, and the latter are undoubtedly influenced by the former; indeed, there is a harmonious functional interrelation between the reproductive organs and the whole endocrine system.

I have recently investigated a case of distrophic adiposo genitalis affecting an epileptic imbecile aged 29 at death. There was no hair on the face, there was polyuria and marked sugar tolerance, there was infantilism of the external genitals, the atrophic undescended testes were no larger than pins and showed microscopically both interstitial cells and spermatogenic cells replaced by fibrous tissue and fibroblasts. Associated with this testicular atrophy was a markedly atrophic pituitary and atrophic thyroid gland, moreover, the cortex adrenalis was much diminished in thickness.

The increase in growth of the long bones of youths retarded in early life is due to retardation of endochondral ossification, and supports the view that the internal secretion of the testis controls calcium metabolism. Similarly, in the female there is a relation between the ovarian internal secretion and calcium metabolism, for removal of the ovaries benefits and sometimes cures osteomalacia. Again, the release of calcium from the pelvic bones during pregnancy and parturition may be regarded as a physiological process brought about by an internal secretion of the ovary, the phosphate of lime thus released being utilized by the mammary gland.

It is generally assumed that the source of the sexual hormone of the female is connected with the development of the Graafian follicle, and that the cells of the zona granulosa and the internal thecal cells of the follicle secrete a specific soluble substance which passes into the blood and determines the female characters. It may, therefore, be supposed that a continuous conversion of primordial follicles into immature Graafian follicles, from earliest infancy onwards, provides a feminizing hormone to counteract the pre-established male dominance in the bisexual cells of the body. This formation of atretic follicles, and subsequently corpora atretica continues until menstruation occurs and maturation with dehiscence of the follicles takes place. I have found that ovaries at birth and in early infancy contain numerous immature Graafian follicles. Should this follicle formation not occur to a normal physiological extent, it is conceivable that, having regard to the selective action of the hormone on the central nervous system, as revealed by Steinach's experiments, there would be a tendency to masculinization especially revealed in mental qualities. The whole of the somatic cells of male and female are, until the dawn of adolescence, engaged in growth and self preservation, in preparation for reproduction and preservation of the species.

Disorders and diseases of the mind have long been associated with two conditions—namely, heredity, and the critical periods of life (adolescence, when the sex instinct matures, and the climacterium, when the sex instinct wanes). These are physiological conditions. Pregnancy, parturition, and lactation in the female are likewise physiological conditions.

Two distinguished Haverham Orientors, the late Dr Ormerod and Sir By in Donkin, have dealt with the subject of heredity in relation respectively to nervous diseases and criminology, based upon wide experience, but neither of these has treated of the relation of heredity to insanity based upon the study of pedigrees, statistical data, and pathological findings.

EVIDENCE OF HEREDITY IN CERTAIN TYPES OF MENTAL DISEASE

There are three types of mental disease in which the naked-eye appearance of the brain do not afford any indication of an exogenous cause of the disorder and loss of mind presented by the symptoms during life. I include them in one group, and they are termed respectively dementia praecox, manic depressive insanity, and involutional melancholia—the two latter may terminate in dementia.

Through the study of a large number of carefully constructed pedigrees by myself and co-workers, extending in many instances to four or five generations, and of statistics based on a card system extending to four thousand related individuals, who have been or were at the time in one of the ten London County asylums, I have come to the conclusion that there is a signal tendency to antedating in respect to these types of insanity, that is to say, if a parent suffered with manic depressive insanity, or a parent or grandparent with involutional melancholia or senile dementia, one or more of the descendants may suffer during adolescence with dementia praecox. In the construction of pedigrees I was particularly struck by the fact that two, three, or even four or five members of the same co-fraternity at about the same age suffered with mental disease—usually dementia praecox, sometimes with manic depressive insanity, not infrequently with dementia praecox and imbecility. This is a more striking proof of hereditary transmission than when mental disease is transmitted in successive generations.

When there is evidence of insanity or epilepsy in both stocks, or a general neuropathic tendency indicative of mental instability, the liability to dementia praecox is greatly increased in the descendants, therefore in advising (as one often has to do) in regard to marriage, evidence pointing to these special forms of mental disease in both stocks, on one side, still more when on both sides even if shown in collaterals, induces one to say definitely from a eugenic point of view that it would be inadvisable—inasmuch as the risk of an insane inheritance for the children is so much the greater.

Moreover, in some of the pedigrees it looked as if there were segregation of unit characters, for I was able to find healthy children who married and had a healthy grown-up progeny in the same co-fraternity with cases of dementia praecox, manic depressive insanity, and imbecility. But, as the late Dr Ormeiod and Sir Bryan Donkin pointed out in their interesting *Harvard Orations*, there are too many complicating factors to permit of Mendelian principles, which are so striking in animals where breeding can be controlled, being applied in relation to mental diseases. I have to omit here the statistical data, but I should like to refer to one result of them, because it supports my premiss. Prior to the war the number of cases of dementia praecox admitted to asylums was about equal in the two sexes, likewise the average age incidence (about 23 years). During the war there were half as many male admissions of dementia praecox as females whose parents were or had been in the London County Asylum. The age of these males averaged 17.5 instead of 23.5, the reason being that those over that age had been conscripted, and I may state as confirmatory of this inference that 14 per cent of the insane in the army were cases diagnosed as dementia praecox.

THE NATURE OF DEMENTIA PRAECOX

By a comparison of the mental and bodily conditions of an acquired mental disease—general paralysis of the insane—with the mental and bodily conditions found in dementia praecox, I shall endeavour to show that in dementia praecox there is a vital defect of the reproductive organs, and of the brain in particular, and probably of the whole body, especially the endocrine glands.

I have investigated spermatogenesis in 108 cases dying in hospitals and asylums at different ages and in different bodily states, including normal death from shock of injury. I have found it active from puberty to old age (81), with individual variations in degree. In cases where severe chronic disease occurred in early life there has been found absence or deficiency of spermatogenesis. In adults dead of shock following accident, tuberculosis, dysentery, broncho-pneumonia, enteric fever, or gangrene of lung, active spermatogenesis was found. It was absent in several cases of prolonged extensive suppuration, and in several cases of cancer. But these were diseases in which an active prolonged cell nuclear proliferation had taken place.

In general paralysis local patches of atrophy of the testes with dense fibrosis occurred in many of the cases examined, but with very few exceptions, in a large number of cases, active spermatogenesis in all stages was found in spite of intercurrent disease. The atrophied patches were due either to gonorrhoeal epididymitis or localized syphilitic inflammatory affection of the testes. The dense white fibrous patches microscopically examined exhibited tubules consisting of thickened basement membrane without Sertoli cells or spermatogenic cells of any kind. The atrophic process was not due to a regressive atrophy, as in dementia praecox, but to a previous chronic inflammatory process. Thus, moreover, was shown to be the case by the fact that normal tubules with active spermatogenesis and Leydig cells could be found in the midst of the atrophied tubules. In spite of this secondary atrophy which affects the testes of many paralytics, the average weight of the pair after removal of the epididymis and tunica albuginea is 8 grams heavier than the testes of dementia praecox, whereas in the majority of cases of dementia praecox examined in emulsion of the testes revealed no spermatozoa, the converse was found in paralytic dementia.

In 27 cases of dementia praecox of which the testes were examined either commencing a partial, or a complete primary regressive atrophy was evident by the morphological and microchemical changes in the spermatogenic epithelial cells and the interstitial cells, with a corresponding thickening of basement membrane and overgrowth of interstitial connective tissue. With a few exceptions these testes of dementia praecox cases showed less evidence of active spermatogenesis than the testes of an old senile case aged 81 at death. In 27 per cent of the cases the interstitial cells showed the pigmentary degeneration found in old age.

I have no time to deal with the very important question of the influence upon the germ plasma of circulating toxins

in the blood. But the study of the testes of 108 cases dying of all forms of disease, and yet, except in dementia praecox and imbecility, showing with very few exceptions active spermatogenesis, appears to me to find a solution in the fact that a barrier of lipid granules, similar in chemical composition to the lipid granules in the cortex adrenalis, was found. These granules consist of a lecithin cholesterol ester. The cholesterol acts as an antioxidant. Now I found in cases of microbial toxæmia that the lipid cholesterol ester disappears from the cortex adrenalis, and some people speak of this gland as antioxidant in function on this account. It seems to prove that Nature will provide as long as it can for the protection of the germ plasma. There is evidence to show that these lipid granules are connected with oxidation processes, and would therefore protect the germ cells against poisons like alcohol circulating in the blood. Whereas in general paralysis clumps of eosin-stained cells could be seen in sections of the testes with a low-power magnification, in the great majority of cases of dementia praecox eosin-stained clumps were not visible, the appearances suggest a failure of these interstitial cells to mature. Fibroblasts and dense fibrous tissue tend to replace the Leydig cells. It is less easy to show the regressive atrophy in the ovaries for various technical reasons, but the study of 100 patients dying in hospitals and asylums led me to the conclusion that there is, similarly to the male reproductive organ, a tendency to regressive atrophy of the reproductive organs in the female in dementia praecox, as evidenced by the deficiency of the chromatin in the nucleus of the primordial follicles, their disappearance and replacement by fibroblasts. The organ shows a sclerotic condition even in many young women suffering with this disease.

To the first volume of *Libro en Honor of Ramon y Cajal's* seventieth birthday I contributed a paper upon "The genetic origin of dementia praecox," giving the clinical history and pathological findings in the brain and reproductive organs of a case of acute dementia praecox. The following is a summary.

There was a family history of insanity on both sides. A brother died in Charing Cross Hospital from a self-inflicted bullet wound of the brain. The testes were sent to me in 1916 as I had asked for the testes of cases dying of injury pronounced regressive atrophy was found. I put them aside after finding they were very abnormal and forgot all about them. Five years later I was asked to see a case at Claybury Asylum of acute adolescent insanity and I was struck by the patient's name and by the history of the brother having died from a self-inflicted bullet wound. I then recollected the name and recognized that it was the brother who had died in Charing Cross Hospital. There was a history of a sister who had been admitted four times to an asylum with manic depressive insanity with sexual delusions. A brother and sister were normal, all the five were highly intelligent. The blood and cerebrospinal fluid examined during life were both sterile and there was only slight leucocytosis. The patient died eleven days after admission. The duration of the mental symptoms was about two months. They were characterized by depression, suicidal tendency and delusions of persecution. He died of heart failure with cerebral congestion and oedema. The testes freed from tunica albuginea and epididymis weighed only 8 grams each which is less than half the normal weight. They presented a uniformly grey instead of a white appearance quite like the organ in advanced cases of dementia praecox. The microscopic appearances of regressive atrophy were in all respects a counterpart of those I had found in the testes of the brother. Sections of the testis revealed tubules in all stages of primary regressive atrophy. Some of the tubules showed only a thickened basement membrane lined by Sertoli cells without any spermatogonia or spermatocytes. In others there were all stages of regressive degenerative atrophy of the spermatogenic epithelium shown by a diminution or even absence of nuclear chromatin in spermatogonia, spermatocytes and spermatids. Where spermatids or spermatozoa were seen there was evidence of a microchemical or morphological change similar to the condition I have found and described in several early cases of dementia praecox. The interstitial tissue displayed an overgrowth of fibroblasts. The cells of Leydig were diminished in size and numbers. The nuclei of the cells were deficient in chromatin, smaller than normal, irregular in shape instead of round. The cytoplasm was deficient in eosin-staining substance and the appearance of the cells generally was that of a regressive atrophy. Pronounced nuclear and cytological changes were found in the cortical neurones generally but the small stellate cells of Cajal were particularly affected.

The microchemical and morphological changes of the nuclear material of the cortical neurones and of the testis in this case indicate in hereditary biochemical deficiency of nuclear material in two structures essential for the preservation of the individual and the species. It has been asserted that the nuclear changes in the reproductive

organs and the cortex of the brain in this disease are due to tuberculosis. In neither of these two young men was there any evidence of tuberculosis, but a strong family history of mental disease on both paternal and maternal sides.

Parallelism of Dementia with Cortical Destruction in General Paralysis

In general paralysis the degree of dementia can be correlated with the degree of decay and degeneration of the cortex caused by the spirochætal infection and the escape of toxins into the cerebro-spinal fluid. There is a proportional extent of chronic inflammatory change, thickening and adhesion of membranes, and atrophy of the convolutions, obvious to the naked eye and sufficient to account for the loss of mind. The parallelism is shown in the fact that if there is well marked speech defect, the left hemisphere will weigh usually 20 to 40 grams less than the right.

Chance is everything, hereditary disposition nothing, in this disease. There is chance of the individual being infected, but only 5 per cent of those infected owing to colonization of the spirochæte in the brain suffer from general paralysis. Likewise chance is everything in the juvenile form due to congenital syphilis.

No Macroscopic Changes in Dementia Præcox to Account for Loss of Mind

In dementia præcox the macroscopic appearance of the brain exhibits nothing abnormal, and even microscopic examination shows little. How can the mental symptoms, then, be correlated with the microscopic changes found in the cortex? Before considering this matter more fully, let me state what are the fundamental symptoms of dementia præcox: they are a weakening of judgement, of attention, of mental activity, of creative ability, the dulling of emotional interest, loss of energy, and, lastly, the loosening of the inner unity of psychic life. The biological view I take is that there is an inherent defect in the fertilized ovum, which shows itself in later life in two structures connected with the primal instincts of self-preservation and preservation of the species, and in those very structures where active nuclear formative processes take place—namely, the cortex cerebri and the reproductive organs.

The brain does not waste in dementia præcox because the axon remains alive and the white matter surrounding the axon does not degenerate. Now the grey matter of the cortex, where all the essential chemico-physical processes take place, according to Donaldson, does not amount to more than one-fiftieth part of the white matter of the cerebrum. Yet if there is functional or structural synaptic dissociation there will result a corresponding failure of psychophysiological processes and disintegration of the psychic unity according to the nature and degree of dissociation. Accordingly, to the naked eye the brain may appear normal, and even microscopic investigation may not disclose in many cases (where the mental symptoms are mainly due to suspension of function) histological changes sufficient to account for the symptoms, as in manic depressive insanity where the patient returns to normal mentality.

It may be asked how we can explain the dissociation (schizophrenia) from a physiogenic point of view. I should say by genetic inadequacy—namely, an inherent defect of the *vitæ propria* of the neurones, especially of those developed from the telencephalon. This portion of the neural tube is the latest to develop phylogenetically and ontogenetically. The countless millions and millions of neurones which constitute the cortex of the cerebral hemispheres have developed from a relatively very small portion of the original neural blastema. At birth further neuronic formation ceases, and further formative activity consists only in growth and extension of nerve cell processes. This continues until at 2½ years the brain has attained a size nearly two thirds of that of the adult. After this growth proceeds slowly until adolescence. There may be a varying amount of pre-natal complete arrest of neuronic development affecting especially those neurones of the highest level which are of evolutionary latest development—namely, the supragranular layer of pyramids and various grades of amentia may be the result. There may be various

degrees of partial arrest of growth and extension of the dendrons, by which there is only incomplete synaptic junction of many neurones of the highest evolutionary level. Such a condition may lead to a failure in the highest level of control without much morphological evidence of a mental defect. Lastly, there may be an inherent lack of durability of the neurones by which they are incapable of performing their functions of storage and transformation of energy during the life of the individual. In normal physiological conditions the neurones should be capable of functioning as long as the whole organism lives. Through an inherent defect they are apt to fail to function at the critical periods of life—namely, adolescence, the climacterium and senescence, physiological conditions of stress—gestation, parturition, and lactation—may occur in the female. Again, such causes of psychological stress as emotional shock, repression and frustration of the sex instinct, causing endocrine disturbance and insomnia, are exciting causes of the onset of disordered functions of the highest level of neurones. If a deficiency of thyroid secretion can arrest structure, and thereby function, producing cretinous idioey, it is not surprising that a deficiency of thyroxine in the blood should cause slowing of nervous function when the growth of the neurones is completed. But the thyroid gland's function is correlated with the whole reproductive endocrine system.

A noticeable histological feature in the brains I have examined of cases of dementia præcox is a morbid change in the nucleus. This change was first described by Nissl as occurring in the cortical cells. It was later described by Alzheimer and by most investigators since. It shows a swelling with often irregular infolding of the nuclear membrane, and deficiency or absence of the basophil staining of the intranuclear network by Nissl stain. In the light of recent researches on the chromosomes in relation to heredity this defect of nuclear chromatin, which occurs also in the reproductive organs, suggests a primary genetic defect.

Now the nucleus of the neurone plays undoubtedly an important part in the function of transformation and discharge of energy from the cell. Although the Nissl granules are artefacts and do not exist in the living cell, yet their presence in the body of the cell and dendrons, and the microchemical reactions they give—showing that they contain phosphorus and iron—indicate that in the living neurone there is a continuous interaction between the surface of the granules and the nucleus by the mediation of the cytoplasm. There is evidence that the granule which is contained in the body of the living neurone and its dendrons, but not in the axon, may form an oxygen surface, and that the iron of the nucleus may act as a catalase now if there is a nuclear failure, as histological observations show, this may account for the neurones being unable to transform and discharge energy along the axon. The neurone is still able to live and its axon is not wasting, therefore the brain does not waste. How, then, can we associate this evidence pointing to a defect in the specific functions of the evolutionarily latest and highest developed level of the brain with the philosophical teaching of Hughlings Jackson? The latter, in his discourse on "The factors of insanity," points out that positive symptoms such as illusions, hallucinations, and delusions, which are so frequently met with in this disease, are evidence of functional activity brought into relief by the negative condition of the highest evolutionary level.

It may be asked, What, then, is the original cause of this abnormal variation in the *inborn vitæ propria* of the fertilized ovum? It has been suggested that syphilitic antecedents may be the cause of dementia præcox, but I have been unable to find proof of this after examination of the cerebro-spinal fluid of a large number of cases of dementia præcox. It is a fact that these diseases do occur in primitive people, only the symptoms such as hallucinations and delusion, are coloured by social usages, customs, and beliefs. Antedating, by bringing on the mental disease at an early age, leads to segregation which together with regressive atrophy of the reproductive organs, tends to stop procreation. Moreover, the lowered vital resistance leads to tuberculosis. 80 per cent of cases of dementia præcox die of active pulmonary tuberculosis, a marked contrast to general paralysis. We observe there is thus a tendency to end or mend a degenerate stock.

THE PART OF HEREDITY IN THE ETIOLOGY OF MENTAL DISEASE

Lastly, from a practical consideration of the subject of insanity, it is very necessary to recognize that the germ cells of every person who is certified as insane and sent to a mental hospital are not necessarily possible potential transmitters of a mental disease. General paralysis of the insane and many other microbial infections leading to disordered mental functions are acquired diseases and are not hereditary. Neither is it right to assume that simple senile decay affecting the brain is transmissible, yet a large percentage of inmates of asylums are sent there on account of senility. These legal administrative conceptions of mental disease must therefore vitiate all statistics in respect to heredity as a cause of mental diseases, because based upon data in which admissions to a mental hospital are in many instances the sole evidence. This does not apply to the same extent to carefully recorded pedigrees, but even these are not free from error, for often all the information that can be obtained is that one or more members of the stock had been in an asylum.

How is the public to know the difference between an inborn tendency to insanity *ab initio* in the ovum, true heredity, and a condition which may arise after conjugation of the male and female germs while the developing embryo is still in the body of the mother? As Sir Bryan Donkin pointed out, congenital disease was confounded with hereditary disease even by medical witnesses who gave evidence before the Royal Commission on Feeble-mindedness. The term "hereditary syphilis" is a misnomer. Much may happen while the embryo is still in *utero*. The normal biological processes of nutrition of the developing embryo may fail, abnormal mechanical conditions may arise in the uterus, interfering with the proper development of the embryo, or mechanical conditions may arise in development of the embryo may arise, interfering with the development of structure. Of all the structures in the body of the embryo likely to be affected by a departure from normal dynamic biological conditions of growth, the great brain or cerebrum is the most likely. The neo-encephalon—the telencephalon, which by rapid cellular proliferation from the telencephalon, which by rapid cellular proliferation grow upwards and backwards to cover up completely the basal ganglia and mid brain to form the cerebral hemispheres. In that process many mechanical failures and accidents may occur, interfering with the vascular supply or nutrition of the rapidly proliferating cells, whereby the process may be arrested altogether, as in *ruencephaly* or imbecile. There is evidence of a possible vascular cause through a lack of correspondence in the normal rate of growth of the dura mater and soft membranes and the longitudinal sinus in a direction opposite to the current of the blood stream in the frontal lobes—an anatomical condition which favours venous stasis. This I have put forward as an explanation of the fact that the frontal lobes of the and atrophy in paralytic dementia, because the spirochaetes, being anaerobic, would develop more easily where there is venous stasis. Again prolonged labour and difficulties in delivery requiring the use of instruments may be responsible for injury of the brain.

Idiots and imbeciles occur in all grades of society (frequently they are the first-born), and it is not at all uncommon to find nothing in the paternal or maternal family history—even when a pedigree can be obtained of three or four generations—to account for this pronounced failure of development of the anatomical basis of mind. The late Dr Ashby considered that 25 per cent of the cases of idiocy and imbecility were due to causes other than heredity.

I feel that the subject is one which still requires an enormous amount of patient investigation before any definite conclusions can be arrived at and I am more than ever convinced of the wisdom of what Harvey's great contemporary Bacon said in his *Advancement of Learning*, *Dime* and *Human* when he wrote "First therefore in this as in all things which are practical we ought to cast up our account, what is in our power, and what not, for the one may be dealt with by way of alteration, but the other

by way of application only. The husbandman cannot command, neither the nature of the earth nor the seasons of the weather, no more can the physician the constitution of the patient, nor the variety of accidents. So, in the culture and cure of the mind of man, two things are without our command—points of nature, and points of fortune."

REMARKS
ON
SENSITIZATION AND DESENSITIZATION
IN SKIN DISEASE

BY
HENRY MACCORMAC, C.B.E., M.D., F.R.C.P.,
PHYSICIAN FOR DISEASES OF THE SKIN, MIDDLESEX HOSPITAL, PHYSICIAN
TO ST JOHN'S HOSPITAL, LEICESTER SQUARE

DISEASES of the skin may be divided for certain purposes into two groups—the first, where the cutaneous manifestations can be shown to be the direct result of the presence in the skin of a specific parasite, as in tuberculosis, syphilis, and scabies, and the second, where the eruption is the manifestation of a reaction to some process which may not have been adequately explained. In the first or parasitic group, because we possess a precise knowledge of the nature of the condition, we can often cure the disease by methods of treatment having as their object the destruction of the causal parasite. This does not apply to the second group, where we may only be dealing with a symptom, as in the case of eczema, urticaria, and other conditions, where, although the local treatment is often successful in removing the eruption, it does not necessarily cure the condition—using the term "cure" in its strict sense—because the factors bringing about the dermatosis may be uninfluenced by the remedies used. This treatment of a symptom is not confined to dermatology, for there are many other complaints, both medical and surgical, where the same method is adopted. Even in cancer,† to take what may be an extreme case, when the surgeon takes any with the knife the primary tumour, and so far as possible any other structures liable to continuation, the highly developed operative technique only removes the result of some mysterious agency, not the cause, for the cause of cancer is still an unsolved riddle. While the discovery of the pathogenetic bacteria made clear the nature of the first or infective group of skin diseases, it left, in the main, the second or symptomatic group unexplained. The doctrine of sensitization offers a possible solution to some at least of these conditions.

The Theory of Sensitization and its Applications

The theory of sensitization is based upon the only experiments of Richet, who, in 1902, demonstrated that when an animal is injected with certain proteins it develops a peculiar sensitiveness to subsequent and often very small doses of the same agent or antigen. The reaction following the second injection has been termed the anaphylactic shock, and may include a general disturbance besides cutaneous phenomena, as in some of the forms of serum sickness occasionally met with following the use of an antigen. It is now known that a great variety of different animal proteins, bacterial products, and even drugs A number of cutaneous eruptions appear to be attributable to this state of sensitization, and this theory of origin has in particular been applied to certain forms of eczema, urticaria, general pruritus, certain erythemas, and possibly seem a long cry from the relatively quiet efflorescences of serum sickness to the violent reactions observed in eczema and the other diseases catalogued above, but there is nevertheless a considerable body of evidence in favour of the view that the eruptions are the result of a special sensitization of the skin. With the object of avoiding a possible source of confusion two preliminary observations may be made.

Abstract of address given to the South Essex Division of the British Medical Association.
† This paper was written some time before Dr Gje and Mr Barnard had published the results of their researches.

In the first place, the names we attach to the various dermatoses may not designate specific diseases, but possibly only reactions arising from more than one cause, and this quality must obviously make the investigation of any one of them the more difficult. This statement is illustrated by consideration of the condition termed "dyssidrotic eczema, or dyssidrosis," recognized by an eruption of deeply seated vesicles affecting both hands, the fingers especially, and sometimes also the feet. It prevails in spring and summer, and this and the tendency to relapse at the same period of each year has led to the belief that sunlight has a direct effect in bringing about the eruption. Dyssidrosis is placed by many observers within the eczema group by reason both of its clinical and histological features. It would therefore appear to belong to the class of diseases which may be attributable to sensitization. Research, however, has shown that certain forms are of parasitic origin and due to the invasion of the skin by one of the ringworm fungi, as in the following case.

The patient a man aged 33 years came under observation in April, 1923. He had first suffered from the condition complained of in 1920, the eruption then attacking the hands and the feet. During the whole of 1921 he remained free, but was again affected in the following year. When seen in April his condition might be described as the classical form of dyssidrosis. As a routine measure the epidermic covering of some of the vesicles was removed with a curette and examined microscopically, and in the specimens thus prepared an abundant ringworm fungus was detected.

Daniel,¹ writing on this subject, states that in 80 per cent of the cases presenting the features of dyssidrosis it is possible to discover a mycelium in the squames, or in the roof of the vesicles, but he does not deny, and others positively affirm, that there does exist a true dyssidrosis, a condition *sui generis*, neither parasitic nor traumatic. In the case recorded above it would have been impossible even for a trained observer to distinguish by simple inspection alone—that is, without the aid of the microscope—between two completely different conditions.

Secondly, it has also to be recognized that although a state of sensitization may be shown to exist it does not necessarily follow that any given eruption is the result of this sensitized state, and two good examples of this circumstance are given by Whitfield² in his Lumlair Lectures. He cites there the case of an infant, aged 3 months, with acute eczema, who was so sensitive to egg that on one occasion, when a small quantity of egg-yolk was included in the food, severe vomiting and diarrhoea resulted, but without in any way affecting the eruption. His second case is similar to the first, for the patient, a child aged 14 months, was also egg-sensitive and also suffered from eczema. When egg was included in the dietary a marked general disturbance followed, with urticaria, but the eczematous eruption remained unaltered. These patients were both sensitized to egg, but in neither case was the eczematous eruption the result of egg-sensitiveness.

To demonstrate that any given eruption is the result of sensitization it is necessary to satisfy two conditions—first, that the patient is sensitized, and secondly, that the eruption is the result of this sensitization. It is not always possible to obtain the complete proof, and, indeed, in a considerable proportion of cases the argument will depend rather upon inference than fact. Sometimes all the conditions can be satisfied, as in the following two cases where the nature of the process and the effects of specific treatment are clearly displayed.

The first is recorded by Vidal, Abram, and Joltrain,³ where a man under their observation became so sensitive to emetine powder that the least contact with it provoked an attack of acute eczema. Knowing the nature of the antigen, these observers were able to desensitize their patient by a series of subcutaneous injections, using at first 1 c.c. of a solution of emetine 1 in 20,000, the strength being gradually increased. By this means the patient ultimately became completely free of his intolerance to the substance.

The second case was brought under my observation by Dr. Jonaiff when casualty medical officer at the Middlesex Hospital. A medical student working in the dissecting room developed formalin dermatitis of the hands, which interfered with his work and caused him considerable inconvenience. It was decided to attempt specific desensitization, and with this object in view the following

procedure was carried out. On November 29th an injection of 1 c.c. of a solution of formalin 1 in 1,000,000 was given, a second injection on December 3rd of 2 c.c. of the same solution caused a flaring up of all the lesions. Further injections were made on December 5th (4 c.c.), December 12th (0.4 c.c. of 1 in 100,000 formalin solution), and a final dose of a similar strength on December 18th. The rash had by this time completely disappeared, and the patient was able to resume his work and has had no further recurrence of the eruption.

While these cases illustrate in the most complete manner the relation of the sensitized state to certain forms of eczema, there are other, if less convincing, methods of demonstrating sensitization in many cutaneous diseases. There are, for example, phenomena preceding the cutaneous reaction—including among other things a fall of blood pressure, diminished coagulability of the blood, and leucopenia—termed by Vidal the haemochlastic crisis. As these are identical with the changes observed in genuine anaphylactic shock, their detection before the appearance of an eruption may be taken as evidence of a condition of sensitization. This method of proof has been used in a case of urticaria under the observation of Pagniez and Pasteur Vallery-Radot,⁴ the more important feature of which may be summarized as follows.

This particular patient was found to be sensitive both to vegetable and animal albumins, and in his case the haemochlastic crisis could be demonstrated before the urticarial rash appeared. But when aliments were ingested from which the harmful substances had been excluded both the cutaneous reaction and the haemochlastic crisis were wanting, while actually a leucocytosis and raising of the blood pressure occurred, such as would normally be met with during the digestive period. The nature of the eruption being in this manner proved, desensitization was brought about by a remarkably ingenious plan. One hour before his repast the patient was made to consume tiny amounts of the foods composing it, thus miniature meal desensitized him, and allowed him to eat subsequently without ill effects.

The protein skin tests have also been used for the purpose of demonstrating sensitization. The technique advocated by Engman and Wander,⁵ which has the advantage over others of avoiding the production of a wheal in urticarial subjects, is as follows. A number of incisions one-eighth of an inch long are made with a sharp von Pirquet knife through the epidermis of the forearm. These are moistened with decinormal caustic soda solution and then the test proteins are applied. A positive reaction consists of a distinct wheal surrounded by an erythematous blush. The well known case of Fox and Fischer⁶ affords striking proof of the practical application of this method. They refer to a man aged 35 years, with chronic eczema of the hands and wrists, who consumed considerable quantities of cabbage, and who, when tested, gave a strong positive cabbage reaction. When this vegetable was excluded from his diet the eczema got well, returning when cabbage was again eaten. He was thus cabbage-sensitive and the eczematous eruption was a manifestation of his sensitized state.

In adopting this method of investigation it is necessary to remember that while an individual may be sensitized to any given protein, it does not necessarily follow that the dermatosis is a consequence. Whitfield's two cases quoted above are striking examples of this fact. The reaction is also open to various interpretations, different observers adopting a different standard of the positive degree. Fox and Fischer appear to have summed up the position in saying that it is difficult at present to draw definite conclusions regarding the true value of the protein skin tests in eczema of adults, and they further add that these tests might prove useful in a small proportion of cases.

Approaching the problem in a novel manner, Cranston Low has, in a series of convincing personal experiments, investigated the effects of sensitization with *Primula obconica*. Before he began his experiments he was, he states, able to handle the plant, and even rub the leaf on his skin with impunity. He purposely scarified a small area on the back of the forearm, rubbing in the crushed

leaf and allowing the juice to dry on the region so treated healed completely, leaving a slight scar, but without itching or dermatitis. Although there was no evidence that anything unusual had taken place, a very definite deviation from the normal actually had occurred—the investigator was now sensitized to *Primula obconica*. Three weeks after the operation recorded above had been carried out the plant juice was applied to the unbroken skin on the same area of the arm, with the result that an intense vesicular dermatitis developed, attaining its maximum in rubbing the plant on the other forearm and the thigh, a characteristic reaction, but of lesser degree, was produced. Two weeks later the sensitized state still persisted, a reaction with the plant being recorded after this interval had elapsed.

The foregoing refers to specific sensitization where the harmful agent can be identified. In these cases specific desensitization can be attempted by administering in various very minute doses of the causal antigen with the object of "re-educating" the tissues. But the investigator will not always be in so favourable a position, and it will often be found necessary to assume that a state of sensitization exists. An eruption, for example, may be considered to depend upon bacterial sensitization of the skin from a focal infection of the teeth tonsils pelvis, or elsewhere the proof of the relationship between the two depending upon the improvement or disappearance of the eruption when the infected focus is identified and suitably treated. Examples of this relationship may be found in cases of lupus erythematosus and urticaria, where, as Barber⁸ has insisted, focal infection assumes a special importance. The following are examples of such a relationship.

A woman aged 22 came under observation with typical lupus erythematosus of the hands and feet of six years' duration which had resisted all the usual methods of treatment. During the course of the disease enlarged axillary glands considered to be tuberculous had developed their removal effected no change in the disease. It was noted that the tonsils were considerably infected and upon their enucleation the eruption cleared up.

Many dermatologists hold that lupus erythematosus should be included among the tuberculides, a group embracing a variety of dermatoses supposed to be due to the toxins carried by the blood from some distant tuberculous focus—the skin lesion. In this connexion it is interesting to note that Dr. Fordyce⁹ has stated that Dr. Cannon, his assistant, logical department of Columbia University, including tissue inoculation from cases of lupus erythematosus into guinea-pigs. Out of thirty cases inoculated, typical tuberculous theory of focal infection of the teeth, tonsils, etc., it implies that some cases of this disease are different from others, and further demonstrates the difficulty of separating apparently similar eruptive types.

Sensitization to bacterial products from a focal infection may sometimes be the cause of chronic urticaria and angioneurotic oedema, as in the following two cases, similar to those described by Buben.

The first patient a woman of middle age had suffered from repeated attacks of giant urticaria over a period of seventeen years during which time she had hardly ever been free from the eruption. It was discovered that certain of the accessory nasal sinuses were infected and when these were drained the urticarial manifestations ceased abruptly.

The second case is even more striking and presents some remarkable features. A woman aged 34 came to hospital giving a history of giant urticaria extending over five years. A search to discover the cause was at first without definite result and it was therefore decided to attempt desensitization by injections of whole blood. She received seven injections with the result that the eruption during the treatment became less and less pronounced and finally entirely disappeared. As during the whole course of her illness she had never been free from some degree of urticaria for more than a few days the hope that she had been cured was entertained. It was therefore extremely disappointing to find six weeks after the injections had been discontinued a return of the eruption in a severe form. Further investigation showed that one nostril was infected the purulent contents of an extremely offensive character. Suitable treatment of this focus resulted in what appears to be final cure.

This case shows the importance of a complete investigation in cases of urticaria, it also demonstrates that a non-specific method of treatment can exercise a real control over disease even when the cause remains operative.

Utilization of the Theory in Treatment

The theories of sensitization would have little more than academic interest were it not possible to utilize in treatment methods of desensitization based upon them. These may be divided into two groups—specific and non-specific. Specific desensitization may be undertaken by giving the sensitized individual a series of doses of the known harmful substance, beginning with very small amounts, which are gradually increased until ultimately a state of tolerance is acquired. While this is the more scientific method, the most extensive investigations often fail to reveal the nature or source of the offending agent, and it may be necessary to adopt the second form of treatment—namely, that has been criticized as empirical, and has been termed from its nature non-specific. This procedure assumes various forms, two of which may be adverted to here.

Non-specific desensitization may be brought about by the comparatively simple method of intravenous injections of physiological salt solution. Some observers attribute the results obtained to the contraindication of the solution with air borne bacteria, and believe that little or no effect follows the use of a solution from which bacteria and their products have been excluded, or removed by double distillation. There would appear to be some reason for this belief, and in the case quoted below the fluid was purposely allowed to become contaminated before sterilization for use.

The patient was a married woman aged 36 suffering from multiple arthritis and lupus erythematosus. No focus of infection could be detected in the teeth tonsils or elsewhere and she appeared to be free from any tuberculous taint. As the condition had failed to respond to a variety of local applications it was decided to attempt to desensitize her by intravenous injections of saline. The first injection of the series amounting to 50 c.c. was administered on September 3rd in all five injections were given at intervals of seven days in increasing quantities up to 200 c.c. of such a character as to interfere with sleep which had been the eruption steadily improved and although it was not completely removed it became of relatively slight degree. The injections were well tolerated and were followed by a moderate febrile reaction, excepting the last which caused the temperature to rise to 101°.

Injections of Whole Blood

Injections of whole blood—a method largely employed on the Continent, but apparently only used to a limited extent in this country—are often brilliantly successful. Auto-hæmotherapy owes its place in dermatology to Rana, who, in 1913 called attention to it and to the conditions in which it might be employed. The technique used by different investigators is not always the same, the following method appears to give satisfactory results and has been adopted in the various cases recorded below.

From a vein in the arm 5 c.c. of blood is withdrawn into a syringe and immediately injected deeply into the muscle high up in the buttock region in the position usually selected for intramuscular injections in this situation. It is important so to prepare the patient that no undue delay takes place between the withdrawal of the blood and its re-injection. If this be neglected the practitioner may find himself in the embarrassing position of having allowed the blood to clot in the syringe and being thereby prevented from completing the operation. If this precaution be taken there is little else apart from the usual aseptic regime, that need be observed, for the procedure would seem to be attended by little discomfort to the patient and to be only in the most cases any subsequent disturbance. I have once met with fever following the injection and once with severe urticaria. The application of the method will best be illustrated by the following series of cases.

Case 1—A female patient aged 75 with severe dermatitis herpetiformis of fifteen months' duration. The nature of the case was manifest from the type of the eruption its distribution including the mucous membrane of the mouth and from the marked eosinophilia. Treatment with whole blood and from the marked improvement in September 1923 and in all seven injections were commenced at weekly intervals. As a result the eruption cleared up and the patient seems to have made a satisfactory recovery. A certain amount of local treatment was carried out at the same time but in view of the duration of the complaint before the special method was undertaken and of the kind of treatment that had been

employed in this period, it may reasonably be assumed that the result should be attributed to the blood injections.

Case 2—A male patient aged 53 with chronic eczema of the hands and forearms existing from early childhood. Almost every recognized application had been used, with never more than temporary success. It was suggested to the practitioner in charge of the case that he should try the effect of a series of whole blood injections. Rapid improvement followed the patient in describing the result stating that his hands which had been severely affected, became like velvet.

Case 3—This case was also an example of eczema involving the face with considerable oedema. The condition had existed on and off for one year, and when seen a severe and acute phase had been in progress during three months. Various methods of treatment such as dieting and local applications had been employed without success. Following a series of whole blood injections the eruption completely cleared up.

Some of the most striking results following the administration of whole blood have been met with in urticaria, general pruritus, and especially in furunculosis. The following cases may be cited as examples of the application of this method in these conditions.

Case 4—A young male who had suffered from chronic furunculosis extending over about three and a half years. He had been treated with vaccines, colloidal manganese, and in other ways but without benefit. He was put on injections of whole blood, and immediately began to improve. After several injections he ceased attending hospital so that his complete history is unknown. As he was most enthusiastic about the treatment and as it inconvenienced him in no way, this may be taken to mean that he has been cured for he was completely relieved towards the end of the period during which he remained under observation.

Case 5 is somewhat similar. The patient a woman aged 23 had suffered from a succession of boils during two months. She was given five injections of her own blood. Improvement began at once, and at the termination of treatment she became, and has remained free from the complaint.

The next three cases to be recorded are examples of the results of this method of desensitization in general pruritus, a condition in which whole-blood injections seem to have a special use. It will be noted that in all the itching had been in existence for a considerable time, and that the benefit appeared to follow directly upon the injection.

Case 6—An example of severe general itching in a woman aged 45. This had been present for three years and had at one time undergone temporary improvement following the extraction of some teeth. The skin was extensively scratched with, in consequence, some degree of secondary pyoderma and lichenization. There was a history of wheals, but these were never seen on the occasions when the patient was examined. In all, six injections of whole blood were given. The itching entirely ceased, and no doubt in consequence of this, both the pyoderma and lichenization disappeared.

Case 7—A woman with severe pruritus and an indefinite history of urticaria of two years' duration. This patient gave a history of three attacks of food poisoning, and as she appeared to have had colitis a vaccine made from the intestinal flora had been used for some time but without effect. On April 20th 1925 she was given an injection of her own blood, following which the itching almost entirely ceased. Subsequently three other injections were given with the result that the patient has remained free from the pruritus.

Case 8—A man aged 64 came to the skin department of the Middlesex Hospital in December 1923 complaining of severe general pruritus of two years' duration. The skin was observed to be generally markedly infiltrated the lymphatic glands in the axillae, groins, supraclavicular regions, and on the lateral aspects of the thorax were enlarged and prominent so much so that Hodgkin's disease was suspected. The blood count was as follows: haemoglobin 82 per cent., red blood cells 4,800,000, white blood cells 12,800 differential count polymorphonuclears 77 per cent., lymphocytes 11 per cent., mononuclears 10 per cent., and eosinophils 2 per cent. One of the glands was removed for microscopic examination and presented the following features. The lymphoid tissue was generally reduced there was increase of the reticular elements but no giant cells were found present. This patient was taken into the hospital and while there four injections of whole blood were given. These were well tolerated except the third following which there was a considerable and prolonged febrile reaction. The result of treatment in this case was striking. The skin gradually became soft and pliable the glands disappeared the patient entirely lost all itching sensation and made a complete and satisfactory recovery.

When we undertake a form of specific desensitization we are, as the facts above demonstrate, in a secure position, but it is not so evident that our methods are of equal scientific precision when one of the non-specific methods is employed. The proof of the nature of the condition would then seem largely to rest upon the results of treatment, the argument being that because the condition for which treatment was undertaken gets well or improves, a desensitizing method having been used, therefore we have been treating a patient who has been sensitized, although the nature of the sensitizing agent or agents remains unknown. But even if we accept this point on admittedly an unconvincing one, we can still point to results obtained which must be satis-

factory both to the patient and the practitioner, whether we label them with a special name or not. The method, like others, has a limited application, but within those limits it would seem to have a distinct value and position in therapeutics.

BIOCHEMICAL CHARACTERS OF CERTAIN BACTERIA

WHEN LIVING IN ASSOCIATION OR ARTIFICIALLY MIXED,
AND WHEN LIVING SEPARATELY

BY

ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.,
DIRECTOR OF TROPICAL MEDICINE, ROSS INSTITUTE, LONDON. LECTURER
ON MICROBIOLOGY, LONDON SCHOOL OF TROPICAL MEDICINE

SOME years ago I noted that when two species of bacteria are living together in symbiosis, or close association, or are artificially mixed, the symbiotic or mixed cultures may present certain biochemical characters which neither species possesses when grown separately. I will limit myself in this paper to touching upon the changes in fermentative properties, quoting only a few examples. The results of the complete investigation will be published at a later date in a more complete paper.

Bacteria Used

The bacteria I have used in my experiments are *Bacillus typhosus*, *Bacillus morganii* (Morgan's bacillus No. 1), *Bacillus dysenteriae* Flexner, *Bacillus proteus*.

The strain of *B. typhosus* was isolated from a case of typhoid fever, and shows all the typical serological reactions and biochemical characteristics of the typhoid bacillus, it is very highly agglutinated by typhoid serum, it does not produce gas in any carbohydrate, it produces acidity in glucose, levulose, maltose, galactose, mannitol, dextrin and sorbitol.

The strain of *B. morganii* was isolated from a stool, it is motile, it produces acidity and gas in glucose, levulose, and galactose, but neither acidity nor gas in any other sugar. In this paper I will refer to it as Strain S.

The strain of *B. dysenteriae* Flexner is serologically and biochemically typical, it produces acidity in mannitol. It was obtained from the Lister Institute.

The strain of *B. proteus* was isolated from a case of enteritis, it is motile and liquefies gelatin and serum rapidly, it produces acidity and gas in glucose, levulose, galactose, saccharose, and glycerol. It produces neither acidity nor gas in lactose, dulcitol, mannitol, maltose, dextrin, adonite, inulin, sorbitol, mesitol, salicin, amygdalin, isodulcitol, or erythritol. As I have stated in other publications, the term *proteus* covers a group of closely allied bacilli and not one species only. The strain I have used is very similar to the variety which I called *paradytiferus* (see Castellani and Chalmers's *Manual of Tropical Medicine*, p. 943). In this paper I will denote it as *B. proteus* (P).

B. typhosus + *B. morganii*

Action on Maltose—*B. typhosus*, as is well known, does not produce gas in maltose or any other sugar, only acidity. *B. morganii* (Strain S) has no action whatever on maltose, it produces neither acidity nor gas. Maltose peptone water tubes inoculated with *B. typhosus* alone or *B. morganii* alone and kept in the incubator for as long as a month never show production of gas. One would expect, therefore, that the mixture *B. typhosus* + *B. morganii* would not cause production of gas in maltose but it is not so. If a tube of maltose peptone water is inoculated with *B. typhosus* and immediately after with *B. morganii* and placed in the incubator at 35° C. for forty-eight

1 Maltose peptone water tube inoculated with *B. typhosus* gas absent. 2 Maltose peptone water tube inoculated with *B. morganii* gas absent. 3 Maltose peptone water tube inoculated with *B. typhosus* + *B. morganii* gas present.

hours, it produces gas in maltose but it is not so. If a tube of maltose peptone water is inoculated with *B. typhosus* and immediately after with *B. morganii* and placed in the incubator at 35° C. for forty-eight

hours, not only will acidity be produced but also a large amount of gas. The same result will be obtained if the two bacilli are previously mixed in plain peptone water and the peptone water mixture inoculated in tubes of maltose. The same result is also obtained if *B. morganii* is added to the maltose tubes twenty-four hours after inoculating with *B. typhosus*, if the interval is more than twenty-four hours then the production of gas is not so constant. When the two bacilli, *B. typhosus* and *B. morganii*, live naturally in close association the same phenomenon takes place, as shown by the following observation. The stool of a suspected typhoid case was examined bacteriologically, using MacConkey's medium plates. An exceptionally large number of white colonies developed; fifteen were picked out and further investigated by replating, etc. Twelve of them consisted of two organisms—*B. typhosus* and *B. morganii*, three of *B. morganii* alone. The mixed cultures derived from the colonies containing both *B. typhosus* and *B. morganii* produced gas in maltose, the cultures derived from the colonies containing only *B. morganii* had no action whatever on that sugar. Mixed cultures obtained artificially by inoculating agar tubes with both *B. typhosus* and *B. morganii* behave in the same manner—namely, when a loopful of the mixed growth is inoculated into a maltose peptone water tube acid and gas are produced.

Action on Mannitol.—As is well known, *B. typhosus* produces acidity only in mannitol, never gas. *B. morganii* has no action—no acidity or gas is produced. The mixture *B. typhosus*+*B. morganii* produced acidity and gas.

Action on Sorbite.—*B. typhosus* alone produces acidity, never gas in sorbite, *B. morganii* alone has no action whatever on sorbite; it produces neither acidity nor gas. The mixture *B. typhosus*+*B. morganii* produces acidity and gas.

Action on other Carbon Compounds apart from the above.—The reactions are seen at a glance in Table I, in which the fermentative characters are given of *B. typhosus* alone, *B. morganii* alone, and the mixture *B. typhosus*+*B. morganii*.

TABLE I

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannitol	Sorbito
<i>B. typhosus</i>	O	O	A	A	A	A	A	A
<i>B. morganii</i>	O	O	AG	AG	O	AG	O	O
<i>B. typhosus</i> + <i>B. morganii</i>	O	O	AG	AG	AG	AG	AG	AG

O=Negative neither acid nor gas A=Acid G=Gas

From the table it is seen that certain sugars and other carbon compounds, which when acted upon by *B. typhosus* alone undergo a simple acid fermentation, and when acted upon by *B. morganii* alone do not undergo any fermentation, neither acid nor gas being produced, are capable of undergoing fermentation with production of gas when they are acted upon by the mixture of the two bacilli. In the carbon compounds in which *B. typhosus* alone produces no acidity and *B. morganii* alone neither acidity nor gas, their mixture produces neither acidity nor gas.

B. typhosus+*B. proteus*

The strain of *B. proteus* used (P), as already stated, has no action on maltose, mannitol, or sorbite; it produces neither acidity nor gas in these substances.

Action on Maltose.—*B. typhosus* alone produces acidity, never gas. *B. proteus* (P) alone produces neither acidity nor gas. Their mixture produces acidity and gas.

Action on Mannitol.—*B. typhosus* produces acidity, never gas, in this alcohol. *B. proteus* (P) has no action on it; neither acidity nor gas is produced. Their mixture, however, produces acidity and gas.

TABLE II

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannitol	Sorbito
<i>B. typhosus</i>	O	O	A	A	A	A	A	A
<i>B. proteus</i> (P)	O	O	AG	AG	O	AG	O	O
<i>B. typhosus</i> + <i>B. proteus</i> (P)	O	O	AG	AG	AG	AG	AG	AG

Action on Sorbite.—*B. typhosus* produces acidity only, *B. proteus* neither acidity nor gas, their mixture causes production of acidity and gas.

B. dysenteriae Flexner+*B. morganii*

Action on Mannitol.—*B. dysenteriae* Flexner produces acidity only, never gas. *B. morganii* has no action on it, neither acidity nor gas is produced. The mixture *B. dysenteriae*+*B. morganii* produces acidity and gas.

Action on Maltose.—*B. dysenteriae* Flexner produces only acidity, never gas, *B. morganii* produces neither acidity nor gas, their mixture produces acidity and gas.

B. dysenteriae Flexner+*B. proteus*

Action on Mannitol.—*B. dysenteriae* Flexner produces acidity, never gas, *B. proteus* (P) produces neither acidity nor gas, their mixture produces acidity and gas.

Action on Maltose.—*B. dysenteriae* Flexner produces only acidity, never gas, *B. proteus* (P) produces neither acidity nor gas, then mixture produces acidity and gas.

TABLE III

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannitol	Sorbito
<i>B. dysenteriae</i> Flexner	O	O	A	A	A	A	A	O
<i>B. morganii</i>	O	O	AG	AG	O	AG	O	O
<i>B. proteus</i> (P)	O	O	AG	AG	O	AG	O	O
<i>B. dysenteriae</i> Flexner + <i>B. morganii</i>	O	O	AG	AG	AG	AG	AG	O
<i>B. dysenteriae</i> Flexner + <i>B. proteus</i> (P)	O	O	AG	AG	AG	AG	AG	O

B. typhosus+*B. morganii*+*B. proteus*

Action on Maltose, Mannitol, and Sorbite.—*B. typhosus* alone produces acidity, no gas. *B. morganii* alone produces neither acidity nor gas. The mixture *B. morganii*+*B. proteus* produces neither acidity nor gas. The mixture of the three germs produces acidity and gas.

DISCUSSION AND CONCLUSIONS

It appears from my experiments that with regard to certain bacteria, when two species live in association or are artificially mixed, their mixture may present certain biochemical characters that neither species possesses when living separately. For example, *B. typhosus* alone produces acidity, never gas, in maltose, mannitol, and sorbite, *B. morganii* alone produces neither acidity nor gas in these substances, the mixture *B. typhosus*+*B. morganii* produces, however, both acidity and gas, although one would expect that by adding to a germ which produces simple acidity, never gas, a germ which produces neither acidity nor gas, there would still be only production of simple acidity.

The phenomenon of fermentation with production of gas of certain substances, such as maltose, mannitol, and sorbite, by adding to a germ which produces simple acidity in them, never gas, a germ which is apparently inert on those substances—that is, produces, alone, neither acidity nor gas in them—seems to depend to some extent on the fermentative powers of the second germ on certain other carbohydrates. For instance, not all bacilli inert on mannitol will cause production of gas in that substance when added to *B. typhosus*, which produces in it only acidity, a condition for the phenomenon to take place seems to be that the added germ, although inert on mannitol, must be capable of producing acidity and gas in glucose. It must be noted, however, that not every organism producing gas in glucose and neither acidity nor gas in mannitol will cause production of acid and gas in the latter substance when added to a producer in it of simple acidity, such as *B. typhosus*.

The subject is very obscure and requires much further investigation, but the fact remains that with regard to certain bacilli the mixture of two species may produce gas in certain substances although one species produces only simple acidity, never gas, in them and the other neither acidity nor gas.

MEETING, BATH, 1925SECTION OF OBSTETRICS AND
GYNAECOLOGY

Lady BARRETT, C B D, M D, M S, President

DISCUSSION ON
THE ROLE OF SURGERY IN THE TREATMENT
OF BACKWARD DISPLACEMENT
OF THE UTERUS

OPENING PAPERS

I—FRANCES IVLINS, M B, M S LOND, CH M LIVER
Clinical Lecturer in Obstetrics and Gynaecology University
of Liverpool

It is probable that no gynaecological ailment has given rise to more discussions or acute differences of opinion than that of backward displacement of the uterus. One of the reasons for this is the fact that in many cases the varied types of backward displacement have not been clearly differentiated or defined. It is advisable to put on one side those classes of case about which everyone is agreed and to concentrate on the types about which there is room for discussion, and if possible to bring forward arguments supported by definite evidence on the pathological significance of a backward displacement of the uterus, and as to the conditions under which a backward displacement requires treatment. Accordingly I shall exclude from this discussion the following conditions:

(1) The mobile retroversion in which the uterus changes its position with the distension of the bladder, and may perhaps be found retroverted during an examination on one occasion, while on another it is in that position of anteversion which is regarded as normal. The misuse of the word "mobile" is the cause of much misunderstanding in its connexion with backward displacements, and I shall use it only for this class of case where symptoms should be absent and no treatment will be required. There is no doubt that in the past a great deal of unnecessary pessary treatment has been adopted for temporary aberrations which would very probably have righted themselves. I would emphasize, therefore, the importance of and necessity for repeated pelvic examinations before any treatment, either operative or otherwise, is undertaken.

(2) The fixed, adherent, painful displacements of the uterus where an infection, either puerperal, or of appendicular origin, or gonococcal, has been or is present.

(3) Retroversion of the uterus associated with prolapse. In both these classes the backward displacement is only part of a more complicated condition, and its treatment will also probably be an incident in the treatment of that condition.

(4) Leaving on one side these extreme classes, I shall direct particular attention to another group, which I shall describe as the immobile, non-adherent, backward displacement, and in this group I shall include both retroversion—namely, the backward rotation of the uterus round a transverse axis passing through the cervix—and retroflexion, which is actually not a displacement, but a change in the shape of the uterus.

In 1912, in a paper read before the North of England Gynaecological Society, founded on 100 cases of backward displacement treated by Gilliam's operation, I expressed the opinion which I had formed as a clinical assistant at the New Hospital for Women—where, though the cases were not uniformly gynaecological, a pelvic examination was made as a routine—that one did not often find a definite retroversion which was not giving rise to symptoms. I have not changed this opinion, but I think it would be useful if a series of cases taken from medical or surgical wards were to be investigated from this point

of view, so that we might have some statistics and not the vague statements which are so frequently made. It would also be helpful if the pathologists and infant specialists in maternity and children's hospitals could give us some idea of the frequency with which a congenital backward displacement is present in stillborn infants and in infancy and childhood. I have asked my colleague Dr Cyron, and he tells me that he himself has not seen one case. I believe investigations have been undertaken in certain ante-natal departments, but in cases of pregnancy it is possible that the normal uterine balance might be unduly influenced by the position of the ovum, which, if situated in the posterior wall, may produce a retroversion in the same way as a fibroid tumour in that situation. Such statistics would carry far more weight than the statements of gynaecologists, who are not usually called upon to examine normal women and girls. It would also be interesting to know on what statistics is based the statement so often made that backward displacements in single women cause no symptoms, and that if present they are due to neurosis.

The large numbers of such patients seeking treatment in whom only an immobile non-fixed backward displacement is present indicate that the condition is pathological, and the fact that in a very large number of these cases the symptoms disappear when the lesion is remedied must be taken as proof against this statement. From a study of several hundreds of cases in women of ages varying from 15 to 55, I am convinced that not only may this type of backward displacement exert a profound influence on the marital relations and reproductive function of the patient, but that it may have an injurious effect on her education, bodily activity, general well-being, and earning capacity. During school life there may be sufficient disability to interfere with regular school attendance or to depress the bodily health just below the standard of healthy well-being necessary for prolonged study and the sustained endeavour necessary to obtain a scholarship. For working women the loss of energy and periodical disablement often entailed by the presence of backward displacement is a very severe handicap. Also, even when the reproductive period of life is over, pathological conditions may be produced which may be the cause of troublesome and unpleasant symptoms in advanced years.

Before deciding the treatment (operative or otherwise) of such a condition, it is necessary to show that the position is pathological, and that it may produce morbid changes, not only in the uterus itself, but in the adnexa and possibly in the adjacent pelvic structures, which may give rise to a definite train of symptoms.

Many anthesis would derive from treatment any woman who complains of backache unless some cause other than a backward displacement can be found. The pain or discomfort is considered to be due to neurosis, and it is believed that treatment will make her worse rather than better. I should be inclined to argue that the presence of a chronic backache or pelvic discomfort is very likely to lead to a neurasthenic condition. Is it not a fact that special attention is now directed by alienists to the presence of pelvic lesions in the inmates of mental hospitals when they are asked *quid sit qua non* that any surgical operation should receive attention before improvement in the mental condition can be expected? If the cure of a backward displacement is part of preventive medicine, the gynaecologists ought not to be behind-hand. I entirely disagree with the view which would treat not the displacement, but only the complications of a displacement, and consider that it should be treated, if possible, before those complications arise. It is clearly wrong also to conceal from the patient the fact that such a condition is present, in the belief that such knowledge will make her neurotic. One is not infrequently consulted by women who after years of sterility have sought advice when treatment is too late, or who have had repeated abortions due to this condition.

CLASSIFICATION

1 *Congenital*—We are led to believe that an infant may occasionally be born with a backward displacement or, more commonly, may develop it during infancy, childhood,

or adolescence, and we occasionally find a small retroflexed undeveloped uterus which is very resistant to treatment. It is extremely difficult to prove that strain has any share in the causation, but I have certainly seen cases where the symptoms dated from heavy lifting (perhaps during the illness of a relative), or after a fall in the hunting field. Again, the condition is common in women who have laborious occupations, such as nurses and factory hands, but in both these it is possible that the malposition is already present, and that the strain only exaggerates it. Women whose occupation involves excessive standing, such as school teachers, shopgirls, or waitresses, certainly come under notice much more frequently than women who can live in easy life.

2. *Acquired*—(a) It is probable that during the early months of pregnancy the uterus in its softened condition may fall back if the ovum is situated in the posterior wall, and the normal equilibrium is disturbed. This would explain some of those cases where, in spite of the total absence of previous symptoms, the pregnant uterus may become incarcerated and retention of urine or a threatened miscarriage be the first abnormal symptom of which the patient may complain. Many of these cases right themselves, though this is less likely should there be any diminution in the conjugate, when the fundus may fall behind the promontory into the hollow of the sacrum, and treatment will be required.

(b) Fibromyomata of the posterior uterine wall or fundus are not infrequently associated with a retroversion, as is also a fibromyoma of the anterior wall when of sufficient size to push the rest of the uterus backwards.

(c) Desmoid tumours and other ovarian or uterine tumours may also be the cause of a backward displacement should they happen to lie forward.

(d) *Dorsal decubitus*. It may happen that during a long illness such as typhoid fever, the flabby uterus may fall back. Should the bladder be overdistended, the small intestine lies on the anterior surface of the uterus, and the displacement may become permanent.

(e) The commonest cause, however, is dorsal decubitus during the puerperium, when the softened uterus falls back under the sacral promontory as involution proceeds. The same incident may happen after an abortion.

PATHOLOGY AND ASSOCIATED PATHOLOGICAL CONDITIONS

The pathology of the retroverted uterus to a large extent depends upon the congestion and back pressure due to the interference with the circulation in the pelvic veins. This congestion, which is much more marked in the displaced puerperal uterus, is nevertheless often present in the nullipara though in a minor degree. The thin-walled veins of the broad ligaments may be recognizably distended, in extreme cases forming a varicocele. Such a condition is likely to cause a sensation of weight and fullness in the pelvis.

Again congestion may lead to increased weight and enlargement of the uterus, both conditions which more easily recognizable in the puerperal uterus, which may even be oedematous. In the same way hyperplasia of the endometrium may result, causing menorrhagia. The sluggish circulation in the cervix leads to a cystic condition, and Nabothian follicles may occur in the presence of a mild vaginal infection. The increased uterine discharge may show itself as a leucorrhoea, or sometimes as haemorrhage between the menstrual periods. An erosion of the posterior lip of the cervix is often present, due probably to the irritating character of retained discharge from the body during uterus. This usually disappears after reposition. The body of the uterus is occasionally incarcerated between the utero-sacral ligaments, and exceptionally a groove can be seen where the ligament presses on each side.

The effect on the ovary is seen first in an oedematous and cystic enlargement. The ovary which may be carried back deeply into the pouch of Douglas drops lower from its increased weight. There is a tendency later for thickening of the tunica albuginea to occur, the ovarian tissue being often replaced by a single cyst. This distention of normal ovarian tissue is one of the most formidable

sequelae of a backward displacement. The prolapsed ovary is in such a position that it is specially exposed to injury. Dyspnoea and thus the pelvic pain may result. The ovary, as it lies in the most dependent part of the pelvis, may readily become inflamed on the surface and adherent to adjacent structures.

As regards the adjacent structures, the round ligaments are usually stretched and lengthened, often attenuated and weak—possibly a cause rather than an effect of the displacement. The utero-sacral ligaments may be much shortened, especially if a retroflexion is present. Then, again direct pressure upon the rectum by the body of the uterus leads to engorgement of the inferior haemorrhoidal veins and the production of haemorrhoids, which may, however, be caused indirectly by the constipation which is a marked feature of these cases. Bladder complications are less frequent, the most striking is retention of urine, associated with the retroverted gravid uterus. Instances of frequency and incontinence occur sometimes in the nullipara, however, in the absence of cystitis and prolapse. One usually finds in such cases a very extreme displacement, the cervix pointing upwards behind the symphysis. On the whole, the bladder is much less frequently affected than the rectum in backward displacement.

SIGNS AND SYMPTOMS

One must be taken to ascertain that the symptoms complained of are due to the retroversion, and to exclude other pathological conditions, such as pelvic inflammation, bacilluria, etc., which may also be present, and which will persist if treatment has been directed only to the displacement.

The symptom most commonly complained of in the presence of an immobile, non-adherent backward displacement is a feeling of lassitude associated with pelvic discomfort and weight. Dysmenorrhoea is common, and is usually premenstrual in type. The patient often states that the periods, which started without pain, have become increasingly painful. This pain is probably caused by congestion and the extra muscular effort needed to expel the secretion. Backache, caused by the drag on the uterine supports, is common, and occurred in nearly every case investigated. Menorrhagia is not infrequent, and is also the result of the congestion and resultant hyperplasia of the endometrium. Leucorrhoea very often occurs. Sterility is common. It is probably the result of the abnormal position of the os uteri, and is often associated with dyspareunia, due to the tender displaced ovary or congested uterus. Iliaic pain may be due to referred ovarian pain.

Associated with the disordered uterine functions are abortions, but these are so common, and so often due to a syphilitic taint and to other causes, that it does not by any means follow that cure of the displacement will result in full term pregnancies. Ertulence and vomiting occasionally occur, and are probably reflex from direct pressure on the rectum.

In later life, in cases of neglected retroversion, the patient may complain of pruritus from an irritative discharge from the hyperplastic endometrium. In such cases adenomatous polypi may be found, which, though innocent, may bleed after the menopause. A purulent discharge may be the intermittent flow from a prometry, due to the retention of uterine discharge by the ill draining organ. This occurs most frequently some years after the menopause, when the uterine muscle has been replaced by fibrous tissue. In puerperal cases leucorrhoea may occur and give rise to rigors and serious symptoms if the condition is not diagnosed and relieved.

ILLUSTRATIVE CASES

Dysmenorrhoea and Menorrhagia

Case 1—A working girl aged 22 had been normal until a severe illness occurred when the periods became excessive and painful, menstrual and premenstrual pain being complained of which became increasingly severe. After six months dilatation and curettage were performed but no relief was obtained. The uterus was completely retroverted and the prolapsed left ovary was converted into a single cyst which was removed and Mayo's operation performed. Two years later the patient writes that she is menstruating quite regularly and without pain.

Case 2—A little girl aged 15 working for a scholarship in a secondary school, was sent from an adjacent county after ineffectual medical treatment. Menstruation had begun at 12 and was painful at the start. It had become increasingly severe and was accompanied by attacks of vomiting and faints. A dilatation and curettage were done together with Mayo's operation. A year later her mother wrote to say that she was completely cured; the periods were regular and free from pain and she had not had to miss school since she had returned after her operation.

Backache

Case 3—A housemaid aged 32 complained of backache, with dysmenorrhoea, menorrhagia, and leucorrhoea. The uterus was retroverted and the right ovary was cystic. After Mayo's operation and puncture of the cyst the patient wrote eighteen months later that the periods were regular and free from pain, and that she was completely cured.

Menorrhagia

Case 4—A nurse, aged 45, complained that the periods had always lasted seven to nine days and were occasionally accompanied by floodings. She was operated upon in 1921. Mayo's operation was performed, and the appendix (not adherent) removed. Four years later her doctor wrote to say that the periods were regular, free from pain and that the operation was a complete success.

Leucorrhoea

Case 5—A woman married twelve years had had one premature infant and had suffered from a continuous discharge and excessive periods for six months. There was a thick mucous discharge from the cervix and the patient had some cardiac trouble. After dilatation and curettage the uterus was fixed in position. The patient reported five years later that she had had no further discharge or excessive periods. When seen in July, 1925, the scar was firm and the uterus in good position.

Sterility

Case 6—A woman, married three years, complained of dysmenorrhoea and sterility. The uterus was retroverted and the left ovary cystic. After dilatation and curettage the left cystic ovary was removed and the uterus was brought up. A year later her first child was born, instruments being used, and two years later a second child—naturally. The periods five years after were regular and painless.

Case 7—A woman aged 26, married six years, complained of sterility and dyspareunia. In 1920, after dilatation and curettage when a thickened endometrium was removed, the cystic left ovary was punctured and the uterus fixed in position. Four years later (July, 1925) the patient was perfectly well and had had two children, one 4 years of age and one 4 months. The labours were normal and her periods were regular and free from pain.

Case 8—A woman aged 26 married three and a half years, complained of sterility, dysmenorrhoea, backache, menorrhagia, leucorrhoea and iliac pain. The uterus was dilated and curetted, the cervical glands showing proliferation and round celled infiltration of the connective tissue. The uterus was brought up. The patient five years later reported that she had had two children, both easy labours, and that she was quite well.

Iliac Pain

Case 9—A married woman aged 37 who had had six children and two abortions complained of iliac pain and a dragging sensation and was sent to Crofton Hospital protracted haemorrhoids and a retroverted uterus were present. She was there examined by Mr. Lister Jones who considered that it was useless to remove the haemorrhoids unless the position of the uterus was improved. The case was transferred to my gynaecological department and the oedematous retroverted uterus brought up after a curettage and removal of the haemorrhoids. The ovaries of which the tunica albuginea was rather dense were scarified. The veins of the broad ligament were markedly varicose. A year later the patient wrote: "I am pleased to say I feel a new woman now. I wish I had come years ago. I get up singing at the top of my voice now instead of crawling downstairs. I can enjoy my meals now and I never have to take medicine. This letter is I think sufficiently descriptive."

Rectal Symptoms

Pressure by the bulky retroverted and retroflexed uterus on the rectum sometimes gives the patient the sensation that the rectum is trying to expel something after the bowels have acted. This was the case with the following patient.

Case 10—A married woman aged 51 who had had three children, the youngest being 11 years of age, complained of severe iliac pain. She had had an appendix operation through an oblique iliac incision five years before but had experienced no relief. The uterus was in a position of extreme retroflexion, the cervix being up behind the symphysis, the posterior lip of the cervix was swollen and congested and marked haemorrhoids were present. At the operation in addition there was a marked varicocoele of the broad ligament.

Frequency of micturition is sometimes produced by pressure of the twisted cervix on the bladder, as in another case in which the retroflexed and retroverted uterus was practically upside down. The patient, a single lady aged 37, had suffered for years from frequency of micturition,

which had been a trouble to her all her life. She could only sleep about four hours. There was no cystocoele, and the x-ray report and bacteriological examination of the urine were negative. Operation has relieved this symptom.

Conditions Present after the Menopause

I do not think it is sufficiently recognized that a backward displacement may cause symptoms late in life.

Case 11—An unmarried woman aged 55 had always suffered from backache and leucorrhoea and had been informed as a girl that she had a displacement but no treatment had been suggested. Pruritus and a haemorrhagic discharge had been noticed after the menopause for two years, and pelvic pain which decreased when there was discharge. The uterus was completely retroverted and could not be replaced as it even under anaesthesia. Several simple adenomatous polyps were present in the cervix and were evidently the cause of the haemorrhage.

In the same way proptosis may also develop, even in the absence of malignant disease.

NEUROSIS

Case 12—A nurse aged 30, had had backache for even years with right iliac pain and leucorrhoea. The appendix was removed for flatulence three years before but the pain remained. A test was ordered by her doctor on the supposition of there being a morbid kidney but gave no relief and her ailments were ascribed to neurosis. At the operation the uterus was found impregnated in the pelvis and the right ovary was enlarged to the size of a Tangerine orange. It had twisted one turn and was converted into a haemorrhagic cyst. A cyst which was present in the left ovary was punctured, the right tube and ovary were removed, and the uterus was brought up by Mayo's operation. The patient wrote two years later saying that her complaint had been completely removed.

TREATMENT

There are two classes of case where the treatment of backward displacement is non-operative and where a cure may be obtained by milder measures.

(1) Pregnancy and the puerperium. In cases of early pregnancy posture or the use of a ring pessary will often remedy the condition. In puerperal case, in the process of involution the uterus may resume its normal position if replacement is effected sufficiently early, and the correction is maintained by the use of a Hodge pessary. In the same way the formation of a retroflexion may be prevented if the softened body of the uterus is hindered from bending backwards during the puerperium.

(2) In some cases where there is grave organic disease present, and an operation is contraindicated. It has been suggested that pessary treatment should be tried before any operation is undertaken to see if the symptoms are relieved. This is rather a clumsy method of making a diagnosis. In young girls it is obviously undesirable, and it is far better to have permission from the parents to confirm the suspected diagnosis under anaesthesia, and to proceed immediately to the necessary operative treatment. The only objection holds in the case of older women, who exhibit in many cases a marked disinclination for pessary treatment. The manipulation involved and the possibility of an unpleasant vaginal discharge are both repugnant to most women, and the fact that the patient's own neglect or forgetfulness may result in ulceration contraindicates this method.

After full consideration of the pathological changes, it is evident that the indications for operation should be widened to include the class of immobile, non-adherent backward displacements in the majority of cases. It is quite unjustifiable to wait for the onset of dyspareunia, sterility, or repeated abortions if there is an operation which will relieve the condition permanently with very little risk to life, and which is not likely to cause complications or risk in child-bearing. Such an operation, I think, we have in the modified Gilliam operation, commonly known as Mayo's operation. Since it possesses the advantage of the original Alexander method as regards the use of a muscular structure which will hypertrophy rather than a peritoneal band which will stretch, but not its disadvantages in the use of the weakest part of the ligament, and since, also, it gives access to the adnexa by the opening of the abdomen, there is much to be said for this operation. As the original Gilliam operation was performed the risk of an internal hernia into the aperture left on each side was obvious, though very few

cases have to my knowledge been reported. Mayo's modification avoids this danger, and as I think, the most physiological method which has been devised. I usually perform it myself through a low median subumbilical incision. After examination of the adnexa, sigmoid attachment, and appendix, I pass a pair of curved forceps between the cut peritoneal edges and extraperitoneal fat to the internal ring, avoiding any injury to the deep epigastric vessels. At the internal ring the peritoneum is perforated, the round ligament is seized in the forceps about 1½ inches from the uterus, and drawn through the aperture in the peritoneum which it fills. A second pair of straight Spencer Wells forceps pinches the rectus sheath and muscle, grasps the loop of round ligament, and draws it out between the skin and rectus sheath, to which the loop is secured by catgut (No. 2 chromicized 20 day Van Horn), about one inch from the midline on either side. Care is taken that there is sufficient but not too great tension to bring the uterus up into good position. I prefer to bring the ligament through the rectus sheath, as it is a firm structure and the movements of the muscle help to cause the round ligament to hypertrophy.

That hypertrophy does occur was shown in a case where sections were taken through the round ligaments some time after such an operation, a hysterectomy being required later. One ligament had given way and appeared as a very attenuated structure, while the other which had held firmly, was a solid muscular band.

In addition, should any stitch trouble occur, any suppuration would be superficial, and the operation is not only practically an extraperitoneal one, but an extramuscular one. I use catgut rather than any non-absorbent ligature material, as experience has shown that only in the most cases does the ligament give way. I think, however, it is necessary to give ample time for adhesions to consolidate and to keep the patients in bed rather longer than is necessary after many other abdominal operations.

I usually puncture any cysts of the ovaries which may be present but do not now resect them, and do not as a rule find it necessary to shorten the ovarian ligaments. If the uterus comes up well it usually brings up the ovaries with it. Examination of many cases later has shown that the cysts do not tend to re-form. Where the surface of the ovary is sclerotic I sometimes scratch, and I think this has had a beneficial effect in some cases.

Special care should be taken in bringing together the cut edges of that part of the rectus sheath between the loops of the round ligaments, which tend to draw apart these cut edges and to allow of the formation of a hernia. To avert this I usually employ some figure-of-eight or coil-screw Holden stitches for the skin and rectus sheath, employing catgut only for the peritoneum. Attention to this detail will usually result in a firm abdominal wall.

Is a dilatation and curettage of value in these cases? I think that it is of very temporary benefit, if any, in cases of backward displacement, but in the presence of hyperplasia of the endometrium it is advisable as a preliminary to a round ligament fixation, as it gives the tissues a chance to make a fresh start.

In this discussion I do not propose to deal with the merits or demerits of operative procedures other than the one I practise, but I should state that I have operated in at least twenty cases where a ventral suspension had been performed elsewhere and have found the peritoneal ligament very much lengthened. In one of these cases the patient a Frenchwoman reported as a symptom the sickening sensation she experienced when walking on her hands and knees, and which was probably due to the nipping of small intestine by this band.

On examining my case books I find that I have performed the modified Gilliam or Mayo operation more than a thousand times, either as a part of the triple operation for prolapse as a part of operations for chronic inflammatory trouble and other conditions, and in about 300 instances for cases of immobile non-adherent backward displacement—the class with which I am now dealing. There have been five deaths among the 1,000 operations—four in very complicated cases, one being from embolism and one from status lymphaticus. Among the 300 non-adherent cases

one death occurred—namely, in a Frenchwoman who came from the invaded area of Northern France and who died from an inoperable gas gangrene infection (*B. perfringens*).

RESULTS

I have endeavoured to ascertain the results of operation on the non-adherent cases, and have been able to trace 200 post-operative cases, of whom 73 were single and 127 married women.

Of the 200 cases traced—

- 136 (68 per cent) report cure of symptoms
- 29 (14.5 per cent) report improvement
- 31 (15.5 per cent) report no permanent benefit
- 4 (2 married 2 single) have died from intercurrent illness not less than eighteen months after operation

Of the 73 single women—

- 44 (60.3 per cent) report cure of symptoms
- 17 (23.3 per cent) report improvement
- 10 (13.7 per cent) report no permanent benefit

Of the 127 married women—

- 92 (72.4 per cent) report cure of symptoms
- 12 (9.5 per cent) report improvement
- 21 (16.5 per cent) report no permanent benefit

It is most interesting to note that contrary to the statement usually made, the results in the single women have been rather better than in the married.

Of the 73 single women 12 have married since the operation these report as follows:

- 5 are cured and have one child each
- 3 are cured and pregnant
- 1 has three children but is suffering from phthisis
- 2 are cured, but have no children at present
- 1 has had another operation, since marriage for sterility

This case was complicated by a chronic appendix

Of the 59 still single—

- 34 report cure
- 15 report improvement
- 2 report temporary improvement
- 8 report no permanent benefit

Of the 127 married women—

- 88 had previously had children
- 39 were sterile

Of the 88 married women who had had children—

- 59 (67 per cent) report cure
- 10 (11.4 per cent) report improvement
- 17 (19.3 per cent) report no permanent benefit

Of these 88 women 37 have been pregnant with 49 live births of which 3 only were instrumental. In addition there were 4 abortions 1 premature birth and 1 is pregnant.

Of the 39 married sterile women—

- 33 (84.6 per cent) report cure of symptoms
- 2 (5.1 per cent) report improvement
- 4 (10.3 per cent) report no permanent benefit

Of the same 39 sterile women—

- 23 (59 per cent) have had children
- 16 (41 per cent) have not yet had children

No woman who had been married more than seven years without having had children has had any after operation but several cases have become pregnant after six years sterility. The 23 women who have borne children have had among them 42 live births of which the first labour in three cases was instrumental. One was a case of contracted pelvis and has had two Caesarean section operations with living children. None have had abortions only but three abortions have occurred among them.

An endeavour has been made to ascertain the cause of some of the failures. In a considerable number of cases a gonorrhoeal infection was responsible others appeared to be suffering from menopause symptoms and others were cases where operation was undertaken many years after marriage.

II—H. RUSSELL ANDREWS, M.D. F.R.C.P.,

Senior Obstetric Physician the London Hospital

With much that Miss Evans has said in her interesting paper I cordially agree, but I cannot endorse everything that she has said.

In cases in which the uterus is not only retroverted but also fixed there can be little difference of opinion: most people will agree that operative treatment is best. I have found, however, that in many cases the uterus is accused of being fixed when it is really freely movable. I have had many such cases sent to me, and have found that although the uterus was said to be fixed it could be moved up into position without difficulty. This mistaken idea that the uterus is fixed is due to one or both of two errors: (1) that vaginal examination is made with only one finger, and (2) that an attempt is made to lift up the uterus only in the middle line. If two fingers are used pressure can be

made higher up and further back, and if, instead of pressing a bulky uterus against the promontory of the sacrum, pessure is made to one side so as to dodge the promontory, many a uterus which is said to be fixed will go up into position easily.

There are some people who think, or at any rate seem to think, that almost every retroverted uterus requires operative treatment, and others who go to the other extreme and say that no retroverted uterus requires any treatment. A speaker at the last British Congress of Obstetrics and Gynecology said that he had not treated retroversion of the uterus for many years. I think that the safe course lies between these two extremes, and that in very many cases retroversion can be ignored, the patient being assured that there is nothing in the condition of her pelvic organs which calls for treatment—in this category come most if not all cases of single women and girls—but that in a small number of cases operation is indicated, and that it will give relief from troublesome symptoms and results. I cannot agree with the idea, so often expressed, that a mobile retroverted uterus of normal size may press on the rectum, causing difficult or painful defecation or piles, as I refuse to believe that an organ 3½ inches long can cause pressure when it is lying in a cavity the diameter of which is 4½ inches. I do not perform operations for retroversion often, but when I do it is usually on account of dyspareunia or of repeated abortions in a woman who has not borne a child. I am old-fashioned enough to believe that the body of the uterus is sometimes tender, and that the dyspareunia and pain caused by pressure in the posterior fornix are due to pressure on the uterus itself and not only on the ovaries, because in some of these cases the ovaries cannot be felt, and when the abdomen is opened the position of the ovaries suggests that they were out of the way of direct pressure. In such cases reposition of the uterus, followed by insertion of a soft ring pessary—I find that I use Hodge's pessary less and less as I grow older—often gives relief from the dyspareunia. In such a case suspension of the uterus by shortening the round ligaments usually gives permanent relief, if the patient chooses to have an operation rather than to continue to wear a pessary. The other class of case is that of the childless woman who has had a miscarriage, or two or three miscarriages, with no apparent cause except that the uterus is retroflexed. It is found in such cases that the uterus does not continue to increase in size after about the sixth or eighth week, and miscarriage occurs at about the twelfth week. The idea that the uterus is poorly developed in such cases is borne out by the miserably poor development of the round ligaments often found on opening the abdomen. In these cases there were usually no symptoms whatever before pregnancy. After a round ligament operation, or, in case when the round ligaments are so thin and weak that they cannot be trusted, a ventral suspension with formation of a septum in the vesico uterine pouch, the patient commonly carries a pregnancy successfully to term. In some of these cases of so-called congenital retroversion, an operation after some years of sterile married life is followed by pregnancy.

There is one point in the technique of the modified Gilman operation on which I wish to say a few words—namely, the practice adopted by many operators of bringing up a loop of round ligament through a small incision in the aponeurosis at each side of the abdominal incision. I have seen several cases in which the patient, some weeks or months after the operation, was alarmed at feeling a small sensitive swelling on each side of the scar, and her doctor to whom she showed it thought that she had a small hernia or two small hernias. In some cases the doctor was right! I have never made this lateral incision, but have always sutured the round ligament to the edge of the aponeurosis on the other side and have never had cause to regret it.

III—R. H. PARAMORE, M.D., F.R.C.S.,

Rugby

THE surgical treatment of retroversion has been a subject for discussion ever since Schultz, about fifty years ago, showed that the normal position of the uterus is that of anteversion, opposed to the urinary bladder, and not vertical

in the pelvis as up to his time had been believed. Whether this discovery on the whole has been an advantage to humanity is a question. In view of the risks which have been run by women discovered to be suffering from retroversion and subjected to operation for its supposed relief it would almost seem that it would have been better had the profession remained in ignorance on this matter.

Schultz's treatment consisted in reposition manually, aided by the sound and sometimes by narcosis—with or without subsequent massage. He used an 8-shaped pessary, part of which, embracing the cervix, was supposed to keep the cervix posterior so that the treatment often failed as a matter of history. In fixed retroversions it did not succeed, and according to Sanger (1888) even when the uterus was not fixed it was far from satisfactory. Sanger found that 20 per cent of the patients were unrelied, and thus alone, he said, demanded that something further should be done. In this way the earlier gynaecologists became intent on the discovery of some operation of easy performance and free from risk, by which intractable cases could be efficiently dealt with, and by which, moreover, pessary treatment in the more amenable cases could be dispensed with.

The earliest attempts were most simple and consisted in cauterizing the posterior lip of the cervix and the adjacent part of the posterior vaginal vault, so that after ulceration the two healed together by cicatrization. Thus it was thought that the cervix, instead of persisting anteriorly, would come to be held posteriorly in the pelvis, and thus the body of the uterus, instead of being retroverted, would come to assume the anterior position.

This, however, was an uncertain method, and Sanger conceived the idea of shortening the utero-sacral ligaments from the vagina, or of inducing an aseptic adhesive inflammation in Douglas's pouch, by packing it with gauze after incising the posterior fornix, from which retraction of the cervix would result. He even conceived the idea of antecurving the uterus, incising the anterior vaginal fornix, opening the utero vesical pouch, and then fixing the body of the uterus to the vagina by silver wire. In this way the cervix would be forced back into its normal position. Or with a finger in the previously dilated uterus, one could pass a loop of silver wire from the anterior fornix through the vaginal wall and anterior uterine wall and out again into the vagina without making an incision.

Schelling (1888), however, performed the first vaginal fixation. By means of a special instrument inserted into the uterus by way of the cervix and made to pierce the anterior uterine wall and the adjacent part of the anterior vaginal wall, he brought a piece of silk from the vagina, through the puncture in the vaginal and uterine walls, out through the cervix, and tied the two ends together. In this way he thought to produce the beneficent anteversion. By care during this operation he thought to avoid the bladder, but had taken no thought of the uterus. Though modified by Zweifel and practised by others, the operation was little employed, though it stimulated thought. It led, after the temporary abandonment of abdominal section in these cases, to Dullens's anterior colpotomy (1892), an operation which came to be extensively employed on the Continent for dealing with intrapelvic pathological conditions, such as ectopic pregnancy, and which was completed by fixing the uterus to the vagina.

Prior to this, in intractable cases, the abdomen had been opened and cases of fixed retroversion treated by removing the ovaries. Koebele in 1877, doing this for retroflexion, brought the ligature ends out through the abdominal wound and thus performed the first ventrifixation. The next year (1878) Muller, having treated two cases of fibroid of the uterus complicated with prolapse by dealing with the stump extraperitoneally to cure the prolapse, suggested treating cases of obstinate retroflexion by fixing the uterine fundus or stump to the anterior abdominal wall. In 1880 Lawson performed ventrifixation twice, and Hennig once. In 1881 Schultz suggested that when a laparotomy was indicated for other conditions the fixation of the uterus to the anterior abdominal wall would definitely prevent the return of old flexions. He even thought abdominal section might be performed for the express purpose of dealing with fixed retroflexions—as, for example, in cases in which

separation of the adhesions with closed abdomen under deep narcosis had failed—but feared that the danger of the operation was too great.

From such beginnings were evolved the operations of vaginal fixation, which led to the interposition operation—an operation to-day of great value in the treatment of prolapse, or of pudendal hernia as I call it—and of ventrifixation and ventriuspension which time has shown to be of no value in cases of visceral extrusion. Whilst in Germany the danger of opening the abdomen led to intravaginal procedures, in this country the invention of Alexander's operation (1884) for the time being settled further inquiry, and for many years now backward displacements of the uterus have been surgically dealt with either by ventrifixation or some similar procedure—by some method of shortening the round ligaments, or by a plecting of the uterovaginal ligaments which Blair Bell some years back advocated and may even now practise.

But the question is whether any operation which inverts the uterus cures the patient. In this respect we must first quote the opinion uttered by Sanger in 1888 and Muller in 1895, that the symptoms of fixed retroversion are due more to the inflammatory state of the appendages and its consequences than to the position of the uterus. Removal of the diseased parts alone—treating the complications—said Gottschalk in 1892, relieves or cures these patients, a forcible inversion does not do more. In mobile retroversion, then, what are the symptoms? In the first volume of my *Statics* I have stated that such cases are symptom free. Certainly I do not know of any pathognomonic symptom, certainly it may be said that many women in whom the uterus is retroverted make no complaint and are quite unconscious of the displacement. If sterility, dysmenorrhoea, aberrations of the menstrual flow, leucorrhoea, and backache are symptoms which women with a retroverted uterus complain of, these complaints are often made by women in whom the uterus is anteverted. That menstruation may be normal and that pregnancy may occur in women with retroversion we know very well, nor is there any reason to suppose that retroversion *per se* causes backache. If the uterus is too big for the pelvis, or if the uterus be retroverted suddenly, pressure symptoms may arise, but even in these cases if the position be not corrected the symptoms often pass away. In other cases there are no symptoms—the condition is discovered accidentally, or the patient is suffering from a real but unobserved disease, the retroversion discovered and all the symptoms attributed to it.

There is another point to notice, which is that, although the operations performed for retroversion do invert the uterus, and so maintain it anteverted for some little time, they are not the cause of a persistent anteversion. Thus Osalis states that the round ligament fixation is but a temporary measure. On four occasions, he says, he had to reopen the abdomen of patients in whom several months to three years previously he had shortened the round ligaments by Alexander's method or by one very similar to Gilliam's. In every case the uterus, although anteverted, was no more held *in situ* by the shortened round ligaments, these had become elongated, in fact they had again partly resumed the sinuous appearance they have in health. The same is the case when ventriuspension has been done, in a case reported by Keller the uterus, anteverted by the operation, was found eight months later, when death after an abortion at three months had occurred, to be again retroverted and a long band had formed.

What then keeps the uterus anteverted after these operations? The causes of the maintenance of the anteverted position I have discussed in volume 1 of the *Statics*. It is the intra-abdominal pressure, the close packing together and compression of all the viscera—a condition of affairs which depends on the functional integrity of the abdominal wall muscles, thoracic diaphragm, and pelvic floor. The pressure within the abdomen maintains the uterus applied closely to the bladder and prevents the waves of pressure which arise within the abdomen during activity, and which are reflected from the hypogastrium into the pelvis from tilting the uterus back. But when the abdominal wall is weak the uterus is maintained less firmly against the bladder, and

times more easily enter the utero-vesical pouch and press the uterus back, the complete retroversion of which in such cases is only a matter of time. On examination we find a retroverted uterus, but the state of the abdominal wall is often overlooked.

In my clinical work I always complete my examination by observing the condition of the abdomen in the erect position. Usually in patients suffering from the so-called symptoms of retroversion one finds that when the individual is lying down the lower abdomen is flat, but that when she stands up it is distinctly bulged. If the pelvic floor aperture is intact, these patients are for the most part cured by fitting an abdominal support. I invariably advise a Curtis abdominal support. It works from before backwards, and increases the pressure within the abdomen; an elastic belt is not so good, at least in non-corpulent women. An elastic belt in such cases simply serves to press on the hips, but what is required is an antero-posterior compression. This assists the circulation—it prevents blood collecting in the large abdominal and pelvic veins, it causes a better return to the heart, there is a better output from the heart, and there is a better supply to the brain, to the limbs, and to the viscera. Thus the whole individual improves from being a cripple the patient becomes an active individual.

Let me quote a case. A doctor brought his wife with retroversion, backache, and vaginal discharge. She had been seen by a gynaecologist a year before—the uterus had been anteverted (so I was told) and a ring inserted. On examination I found a flaccid abdomen, and a ring in the vagina. After removal of the latter I found the uterus retroverted and, with a speculum, the cervix in the state of erosion. I treated the erosion, painted it with picric acid in spirit, prescribed a douche of chlorine, and ordered a Curtis abdominal support and a tonic medicine. The backache has all gone, the patient is in the best of health, but the uterus is still retroverted.

The weakness of the abdominal wall so common after pregnancy is the cause of many symptoms which have been attributed to retroversion of the uterus, thus dyspepsia, indigestion, and neurasthenic complaints are common in these cases. They vanish with proper treatment. Especially does the backache disappear. In the *Lancet* a year or two back a paper of mine appeared on this subject of backache. I referred to its surgical treatment, but this did not consist in a measure affecting the position of the uterus. In cases in which the Curtis support does not do well, as in parous women with mailed and persistent separation of the recti and considerable bulging of the whole abdomen, in which, with a Curtis support, the abdominal wall above the instrument rolls out over it, or in other cases in which great bulging of the abdominal wall muscles in the iliac regions occurs when the woman lying supine raises her head and shoulders, I have in one case of the former plicated the stretched aponeurosis between the recti, and in one case of the latter done a bilateral Lothuisen's operation with the best results. Both were advised to wear a Curtis support subsequent to the operation. The former patient I saw recently and scarcely recognized her, so much was she improved. Instead of presenting as a flabby inert individual, she appeared as a vigorous woman, vastly improved in health. The other patient, though suffering from some intracerebral thrombosis (so it seems), is up and about and now complains no more of her backache.

I have performed Gilliam's operation a few times for retroversion, but confess I have done so mainly for experimental reasons. The patients have expressed themselves as much improved, but it must be remembered that when a patient goes through the ceremonial of an operation she is impressed. There is the danger of loss of life and the return from anaesthesia. There is also the knowledge that the surgeon is a capable person, that he believes she will be better. This, combined with the rest in bed after operation, the cheery note maintained in the wards, and the desire to get well, plays some part in the cure. But especially is this ensured if the abdominal wall be good, or if such measures are taken to ensure a good intra-abdominal pressure. Such are my opinions on this matter; the surgical treatment of retroversion *per se*, I think, is a secondary affair.

GENERAL DISCUSSION

Professor W C SWANN (Bristol) said that in the majority of cases uncompleted retroversions produced no symptoms, and that in many of those cases in which symptoms usually attributed to retroversion were present some pathological lesion insufficient to produce evidence on examination was present. He recalled the period when the outfit of a gynaecologist consisted in the main of pessaries of varied and extraordinary shapes, the vast majority of which were now to be found only in museums. Surgical intervention should be restricted to those cases in which a definite departure from the normal other than mere displacement was present, or in which the displacement could be shown to be the cause of some definite disability. The uterus was a mobile organ, in fact almost the most mobile in the body in certain directions. No surgical procedure which produced absolute fixation or limitation of movement beyond the physiological extent should therefore be adopted. The mild, often chronic, infections which he believed were most often responsible for the symptoms attributed to retroversion should be dealt with by other means than major surgical operations. He suggested that these slight infections were much commoner than was generally supposed in women and girls who did not present any definite symptoms, and who therefore did not consult a doctor. He suggested that Dr Ivens and her women colleagues might be able to obtain valuable information on this point. The first aim should be to render the anatomical relations of the uterus such that intra-abdominal pressure could exercise its normal function as described by Dr Paramore. The structures which normally played the most important part in restoring the uterus to its position after physiological displacement were the round ligaments, and these should be shortened so as to restore to them their lost capacity for influencing the position of the fundus. If the isthmus of the uterus was displaced to the point of its normal position, the utero-sacral ligaments lengthened, and the pouch of Douglas unduly deep, the shortening of the utero-sacral ligaments and the obliteration of the pouch of Douglas would materially assist in attaining the object aimed at.

Mr F W MARLOW (Toronto) stated that he believed retroversion of the uterus was fairly common in girls and nulliparous married women, but in the great majority of such cases there were no symptoms and consequently no treatment was indicated. In his opinion retroversion seldom caused symptoms unless there was some accompanying descent of the uterus of a minor or greater degree, and in the vast majority of cases in which symptoms were present retroversion and descent could not be dissociated. In all cases it was most important to overcome the descent by well arranged plastic vaginal procedures and at the same time to bring the uterus into a position of anteversion so that the normal state of pelvic mechanics was restored. Regarding the use of pessaries, Mr Marlow stated that they could often be used with decided advantage as a temporary measure in cases in which for some reason an operation could not be proceeded with, and for testing out cases in which nervous symptoms were marked. Care must be taken that the pessary was suitable and well fitting in each case, and the hard rubber pessaries as purchased in the shops were seldom applicable without remoulding. Pessary patients must, of course, be well instructed and kept under regular supervision.

Dr FANQUHAR MURNAY (Newcastle-upon-Tyne) said that opinion had undergone a profound change, and those who still performed such operations were now severely criticized and asked to provide proof of justification for them. He considered that Dr Ivens had failed to prove her case, and he strongly supported what Dr Russell Andrews had said. The Newcastle school had for many years taught that such operations were not justifiable, and he had seen many women who had derived no benefit from the operation. With regard to the cases mentioned by Dr Russell Andrews—which were admittedly rare—he would certainly consider performing the operation if they failed to respond to simpler forms of treatment. He strongly deprecated the all too prevalent habit of giving women, especially those who

were young and nervous, a detailed description of their pelvic organs. Many women, in his opinion, suffered great mental anguish after being told that their uterus was displaced, "kninked," or "dropped," and he instanced the similar dread experienced by nervous patients who had been given exact details about their blood pressure.

Dr W A ANDERSON (Queenstown, New Zealand) asked whether patients who had symptoms due to retroversion were still beneficially treated by dilatation and curettage together with the plastic operation of the pelvic floor described by Footehill.

Dr IRITH MURRAY (Liverpool) contended that those who carried out a lesser procedure for the treatment of any symptom or group of symptoms were in a better position to judge whether enough had been done than were those who adopted a more extensive procedure. He included himself with those who only infrequently operated by the abdominal route for mobile retrodisplacements, and found no reason to be dissatisfied with his attitude. He considered the indications to be strictly limited to three groups of cases—namely, subinvolution with retroflexion, dyspareunia, and sterility. He was not sure that he could wholly justify his inclination towards abdominal operation for the first of these, but was under the impression that it was a successful supplement to a curetting in aggravated cases, and that it produced an earlier reduction in size than when a curetting alone was done. Dyspareunia resulting from prolapsed appendages could be very efficiently treated by bringing the fundus forward and retaining it there. For sterility associated with retroversion he preferred a pessary, but was ready to operate should the patient have any disinclination for that form of treatment. With very few exceptions the remaining cases coming for treatment of symptoms believed to be due to a backward position of the uterus were in reality suffering from either general debility, constipation, visceroptosis, scoliosis, or functional hyperactivity of sexual origin. In the last of these a curetting might sometimes help, but there was certainly no indication for anything further. He preferred a ventrisuspension, with a mesial septum dividing the utero-vesical pouch, to any method of shortening the round ligaments, it could be quickly carried out through a very small incision, was absolutely safe, and was reasonably permanent.

Colonel V B GREEN-ARMITAGE (Calcutta) quoted Sydney Smith to the effect that the further he moved towards the West the more sure he was that wise men came from the East. He himself was more certain that the wise women were in the East, for simple retrodisplacement of the uterus had been known for thousands of years in the literature of the Jews, Copts, and Hindus. But this condition only called for investigation and treatment if it was complicated by sterility, dyspareunia, or prolapse. In the East the abdominal pressure was well maintained by an excellent abdominal musculature. Moreover, massage and postural treatment had been recognized for thousands of years as a most adequate means of dealing with minor pelvic discomfort. But should any of the three symptoms above mentioned be present, then, and then only, it would be found that the Oriental woman would come for operative treatment, vaginal or abdominal. He was of opinion that to day in the West the glamour of a laparotomy was so greatly attractive to the young surgeon that he lost sight of the dismemberment necessary, and he feared, therefore, that a very large number of needless modified Gilliam operations were performed, to the detriment of scientific surgery.

Mr A E CHISHOLM (Dundee) asked Dr Russell Andrews for details of the operation for retroversion of the uterus which he employed. He made a plea for the operation of interposition in cases in which there was associated prolapse and cystocele with retroversion. He made mention of Dr Hugh Ferguson's modification of the Alexander Adams operation, and advised that the round ligaments should be made to burrow between the layers of the broad ligament to obviate the risk of internal hernia.

Mrs B L W STAYLAND (Hereford) strongly advocated exercises for increasing the strength of the abdominal and pelvic floor muscles. Exercises were far preferable to a supporting belt.

Mr D C RAINER, Vice-President (Bristol), agreed with Dr Andrews that retroversion in a non-gravid uterus causing retention of urine must be very rare. Cases of retroversion causing symptoms after the menopause must be very uncommon, and if the abdomen was opened in a case of this sort he thought hysterectomy would be the wisest procedure.

Dr RUSSELL ANDREWS then explained the technique of the operation he practised himself.

Miss IVENS, in reply, stated that she had only considered in her statistics cases of non-adherent backward displacement where the uterus was constantly found in a backward position. She thought a curettage was useful in cases of hyperplasia of the endometrium in nulliparae, as well as in cases of subinvolution. She was surprised that Dr Russell Andrews had not found backward displacement to occur fairly frequently in nurses. She emphasized the part played by the appendix in the causation of leucorrhoea in nulliparae. She thought that Alexander was responsible for the idea of utilizing the round ligaments in these cases, and that Gilliam, though his operation was imperfect, had indicated a method which, with an extraperitoneal modification, had led to a very satisfactory operation. She herself was of opinion that, when the symptoms were not relieved by operation, her diagnosis needed revision. She believed in telling the patient or her guardian what was the cause of her symptoms, as she constantly came across cases where patients sought advice after years of sterility, when it was too late for treatment to be of service. She agreed with Mrs Stallard that exercises for the abdominal muscles might be useful. Miss Ivens assured Colonel Green-Armstrong that she did the operation when she considered it advisable, and did not think many experienced gynaecologists would do it unnecessarily. She had been interested in the subject for a great many years, and thought this accounted for the large number of cases she had been called upon to treat.

191. PATHOLOGY AND TREATMENT OF EROSION OF THE CERVIX

BY

GILBERT I STRACHAN M.D., M.R.C.P.,
F.R.C.S. ENG. AND ED.

Asistant Gynaecologist Cardiff Royal Infirmary, First Assistant
to the Professor of Obstetrics and Gynaecology, the
Welsh National School of Medicine

EROSION of the cervix is undoubtedly the lesion most commonly met with in the female. According to varying estimates it is present, in greater or lesser degree, in 75 to 80 per cent of puerperal women and in about 25 per cent of nulliparae. Although considerable attention has been paid to this condition in recent years it is doubtful if, even yet, it has received the detailed study which it deserves. As the lesion may be difficult to cure, may cause much psychic distress, may be followed by grave sequelae, and as leucorrhoea, the main symptom, is often accompanied by physical and mental discomfort it seemed to me that the condition might profitably be discussed to day.

PATHOLOGY

The lesion is essentially inflammatory, and when first seen the inflammation is usually chronic in type. It must be remembered that the vaginal canal, communicating as it does with the exterior, normally harbours bacteria in the lower part but that the pathogenic action of these bacteria is kept under control by the acid reaction of the vaginal secretion due to the presence of Döderlein bacillus. Again, the vaginal mucosa is lined right up to the external os by stratified squamous epithelium which is resistant, it contains no glands where organisms might

penetrate and lodge. The cervical mucosa, on the other hand, is covered with columnar epithelium, which is invaginated to form numerous deep racemose glands.

The conditions, then, favouring infection of the cervix from below are either a lack of continuity of the squamous epithelium as occurs in a cervical laceration, or some factor which renders the reaction in the vaginal alkaline, such as the presence of lochia, both these factors are frequently present after labour. But erosion of the cervix may occur in nulliparae or even in virgins. In the latter case the condition is said to be due to the persistence of the foetal conditions in the cervix, where the gland bearing columnar epithelium is not confined to the cervical canal but extends partly on to the portio, producing a red area around the external os. This is known as a congenital erosion, such in erosion is usually of slight degree. But in many virgins, and also in nulliparae, the causative factor is probably more often anaemia or some other form of general ill health, which reduces the acidity of the vaginal secretion and lowers the general resistance to infection. In nulliparous non-virgins and in some puerperal women gonorrhoea is the cause of infection and in the former of these classes the gonococcus exercises its well known ability to penetrate and infect an intact mucous surface. In most cases, then, a greater or lesser degree of cervical laceration is present, but it is to be emphasized that the extent of the subsequent erosion bears no relationship to the degree of laceration. A very small laceration may be followed by extensive erosion and vice versa. It is the violence of the infecting organisms that counts.

The process of infection can be described briefly. The subepithelial tissues become hyperaemic and oedematous, with redness and swelling of the cervical mucosa. This is accompanied by an increase of the secretion from the cervical glands, which appears clinically as a mucoid or mucopurulent secretion to which the general name of leucorrhoea is given. As a result of this subepithelial infiltration a certain number of the squamous epithelial cells surrounding the external os are raised from their bed and finally cast off, leaving a red raw circle round the os. This raw area becomes covered by columnar epithelium which has been stimulated to grow out from the cervical canal. Racemose glands are carried out along with the epithelium, and may proliferate greatly, producing the condition described by Liden as pseudo-adenoma, and usually called an erosion.

Most authorities stress the point that this so-called erosion does not represent an ulcer, and that the red strawberry appearance is due to the deeper inflamed tissues being seen through the columnar epithelium. But parts normally covered by columnar epithelium—the uterine cavity or cervical canal—do not present this red appearance. Again, a more or less dense infiltration of lymphocytes is always found below the surface, indicating the presence of a chronic infection, and this would hardly persist if the surface were completely covered over. Further, on examining microscopically a large number of such cervixes, I have always found some solution of surface epithelium. There is in every section examined an area between the columnar covering on the one side and the squamous on the other where there is no surface epithelium and where the condition represents essentially a chronic granulating area.

The racemose gland ducts may become blocked by unsuspected secretion or constructed by periglandular fibrosis and the result, forming retention cysts which may in time impinge on the vaginal surface of the cervix, forming the well known Nabothian follicles. The chronic infection is likely in time to extend beyond the mucosa into the muscular tissue of the cervix, causing fibrosis which at first produces hypertrophy, but later leads to shrinkage of the cervix. Again, lymphatic spread is almost invariable and leads to thickening of one or other broad ligament. In a number of cases a definite fibrous scar can be felt extending from the laceration over the vaginal fornix. The utero-sacral ligaments are also commonly involved, and on pulling the cervix forwards resistance is felt and the patient cries out with pain. Prostatitis is often present in these cases, and may be due to conditions similar to those that

produced the cervicitis, but it is a separate condition, and the cervical erosion requires different treatment from the endometritis.

The infecting organism is usually one of the pyogenic cocci. Staphylococci and streptococci are the most common and are often present together. *B. coli communis* is a frequent cause, also the gonococcus. The last named may be very difficult to isolate in surface swabs, as it readily penetrates to the deepest parts of the cervical glands. The lesion produced by it, however, differs in no way clinically from that produced by the other organisms, and requires similar treatment.

The later sequelae of cervical erosion are important and may be serious. Space forbids more than their mere mention. They include general ill health due to constant leucorrhoeal discharge and absorption of toxins from the cervix, chronic pelvic pain and backache due to infection of the pelvic cellular tissue, and mental distress or even derangement. Sterility and a tendency to puerperal infection are quoted, but experience does not support this. The most important sequel, however, is undoubtedly carcinoma. The continued irritation of the epithelium of the damaged mucosa would appear to be a predisposing factor in the production of epithelioma of the cervix. This condition usually occurs in a puerous woman who is likely to be the subject of cervical erosion, in many cases the transition from the one condition to the other can be traced clinically and histologically, and there is little doubt but that erosion is the main predisposing factor in the production of carcinoma of the cervix. It is noticeable also that the carcinoma usually spreads most rapidly into the broad ligament which has been thickened and infiltrated by the spread of chronic sepsis from the erosion.

TREATMENT

Prophylactic treatment consists in giving a patient, and especially a puerperous patient, plenty of time in the first stage of labour to enable the cervix to be fully dilated normally before any manipulation such as forceps application is performed. If this were observed more fully than is the case a very large proportion of cervical erosions would be prevented, but not all, as the very smallest breach of continuity of surface may be followed by erosion, and in many cases it is impossible to prevent a small laceration during dilatation. There is little tendency for such a laceration to heal, as muscular contraction pulls the lips apart. Thus a certain number of small lacerations may not be evident at birth when the cervix is oedematous and ptulose, but when obvious laceration has occurred it should be accurately sutured with catgut in every case.

Curative Treatment

It is to be kept in mind that what we have to treat and heal is a chronic infective process which has penetrated to the deep glands or to the muscular tissue, and that when this is done the secondary parametric infiltration will to a greater or lesser degree resolve itself. The numerous methods of treatment suggested from time to time indicate how difficult it may be to effect a cure. The main lines of treatment recommended are the application of antiseptics, cauterization or electric treatment, radium, vaccine therapy, and operative treatment.

1 The antiseptics employed are usually 10 per cent formalin, iodized phenol, or 20 per cent argyrol. They are applied on mounted Playfair's probes after exposure of the cervix and removal of the green cervical mucus with liquor potassae. Assistance is necessary, the procedure has to be repeated two or three times weekly for several weeks, and the patient is apt to cease attending. Again, it is not to be expected that any surface application will penetrate to the deep glandular tissue far less into the muscular tissue, and the usual result of these applications is improvement during treatment with future relapse. Only in slight and early cases is cure to be expected.

2 Puncture with the actual cautery at a dull red heat causes improvement in many cases. It is important to puncture every Nabothian follicle with the cautery. Dickinson, Halli, and others have elaborated a technique of radial cauterization of the cervix from the external os.

An electric cautery is used, and the process is repeated twice weekly for four or five weeks. Dickinson describes this as "office treatment," and reports a large percentage of cures. It is the usual experience to find improvement after cauterization, but cure is not common, and so far as the writer can judge, even if successful the cervix is still left prone to the development of carcinoma. The passage of 20 m. of electricity through the cervix was advocated by Slown and Someville fifteen years ago. Good results were reported, but this line of treatment has never been generally adopted.

3 Radium has been used, especially in America, in the treatment of erosion, and while it is too early to pass an opinion it is probable that this is a most useful avenue to explore.

4 Autogenous vaccines have been used by Eyre, Gemmell, and others, but without appreciable benefit.

5 If the condition is advanced operation is usually required sooner or later, and various procedures may be adopted.

(a) Uterine curettage can improve only the associated endometritis, and cannot sensibly affect the cervical erosion. The ordinary curette cannot penetrate the hard cervix sufficiently to be effective, and any improvement produced will be slight and evanescent. Berkeley and Bonney recommend scraping the cervix with a Volkman's spoon, and this measure, combined as it may be with cauterization, is certainly effective in some of the less advanced cases. In a chronic condition which has penetrated to the glands and muscular tissue, however, it is difficult to see how all the affected tissue can be removed, and the usual experience is that, in such cases, recurrence takes place after a period of improvement.

(b) Pachelorrhaphy may cure the erosion, but the endocervicitis is likely to remain. There is a considerable tendency for the wound to break down after this operation, and the original lesion is re-formed.

(c) Removal of the affected mucosa constitutes the only reasonably certain method of cure. By this means the erosion and the affected mucosa of the cervix, usually the lower three quarters of an inch, are removed, and the healthy lips of endocervical and vaginal mucosa approximated by catgut sutures. In advanced cases amputation of the cervix is called for, but usually the type of plastic operation described by Bonney suffices, where the affected part is removed after reflecting the vaginal mucosa, which is afterwards incited to form a new cervical canal. Strimmdorf has introduced an operation of this type where he cuts from the periphery towards the cervical canal—the "coming out" operation—but the principle is the same as the other Schiöeder's operation, where the cervix is split bilaterally and the affected mucosa removed, has been found by the writer most effective in nulliparae with resistant leucorrhoea.

These operations are radical, but, in my experience, represent the only speedy, effective, and reliable prospect of cure. Regarding future impregnation and labour, Matthews, Cutis, and others declare that the former is not prevented and the latter not obstructed. I have personally attended many cases of labour after such a removal of cervical tissue, and in neither case was there any difficulty with the first stage, while examination later revealed no fresh lacerations.

It is to be emphasized that this lesion is essentially a precancerous condition of the cervix, it is only by prevention or cure by one of the methods described that the onset of carcinoma can be effectively prevented.

DISCUSSION

Mr D. C. RAYNER (Bristol) congratulated Dr Strachan on his paper, particularly in view of the opinions expressed at the first session of the Section as to the importance of this question. Mr R. H. PYRAMORE (Rugby) said that he had treated cases successfully with picric acid applications, and they had remained cured. He had also used the Paquelin cautery. Another speaker classified cervical erosions as (1) those of origin from tears, (2) those of inflammatory origin with no solution of continuity. The true ulcer type were cured by repairing the laceration, the

inflammatory lesions yielded very satisfactorily to treatment by glycerin tampons applied for twenty-four hours twice a week. He asked whether there was any added danger of cancer occurring after the use of the cautery. He also inquired as to the frequency of tuberculous infection of the cervical uterus.

Dr. STRACHAN, in his reply, said that piecic acid and tampons were both well recognized forms of treatment, but he had not found them give much relief. In severe cases nothing short of removal would suffice. It had to be proved whether the cautery could prevent cancer, and, on the other hand, they knew that cancer tended to grow on the scars of burns. By no means every case of laceration became cancerous, but nearly all cancers supervened on lacerations.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

OBSTRUCTION DUE TO GALL STONES

The note by Mr. Ross Smith on September 12th (p. 479), coinciding with the date of our second case in a few years, suggests that the condition may not be so much rare as unreported.

Case 1. A man of 62 with an old gall stone history, had obstruction about the middle of the jejunum. The symptoms were those of complete obstruction alternating with periods of relief, and passage of flatus—the stone acting as a ball valve (the stone measured $3\frac{1}{2}$ by 3 by 2 cm). After operation the patient did very well for twelve hours, then suddenly collapsed and died just as the house-surgeon came in response to an urgent call from the ward.

Case 2. A woman aged 65, had a history of gall stone of a month's duration. The stone was impacted about 9 inches from the ileo-cæcal valve. She lived for four days, and died suddenly after taking a dose of castor oil. This was in February, 1920.

PROTEIN SHOCK IN EPIDEMIC ENCEPHALITIS

In the article 'Some notes on epidemic encephalitis' (BRITISH MEDICAL JOURNAL, October 10th p. 644) Dr. A. Cuddeh Robb arrives at the same conclusion, from the treatment of a large number of cases, as that expressed by Professor Hall: 'At present any reliable therapeutics, either for the disease itself or for its many after results, does not exist.' My own experience agrees with that of Dr. Robb, but in the case I now describe protein shock therapy seems to have played a useful part, and the leucocytosis evolved to have been associated with, if not to have caused, the elevation from profound stupor to normal consciousness.

A girl aged 15 contracted encephalitis in December 1924. Three weeks after the onset she became suddenly worse and almost comatose. Some improvement took place but she remained lethargic and the temperature was irregular until April 3rd, when Dr. Vaughan of Broadway invited me to see her with him. I found her lying on her back with her knees bent. She took no notice of her surroundings but reacted being examined. She only spoke to utter single words such as mother, orange, chocolate. Her whole body and limbs were in a state of spasmodic contraction. Flexibility of the neck was clearly exhibited. The tendon reflexes of arms and legs were very active. The right pupil was larger than the left. She continued in much the same state but it became more difficult to get her to take food and she had to be fed by the stomach tube from the middle of May until she was admitted to Cheltenham General Hospital on June 6th. She was then in a condition of deep lethargy, lay in bed with her eyes tightly closed and her four limbs in flexor contraction. She could be stimulated to groan or cry out by pinching the skin but could not be got to perk, she passed urine and faeces under her and had to be fed by the stomach tube. On June 26th her condition had not altered and she was given 2 drachms of strychnine in mill by intramuscular injection. The total leucocyte count rose from 5,600 per cmm the day before admission to 17,200 the day after injection and the percentage of polymorphs rose from 55.6 to 75.2. There was

little change in her clinical condition but her eyelids flickered and she seemed to me less deeply lethargic. On July 3rd she was given a second injection, this time of 3 drachms of milk. The leucocyte count the day before the injection was 5,200, and the day after 51,800. The relative percentage of polymorphs rose from 55.5 to 78.5. This time she felt the prick more gave a slight scream, and for the remainder of the day held herself as if in pain at the site of the injection. She also opened her eyes and looked round for the first time since her admission to hospital.

On July 8th she was given a third injection of milk, the dose being 3 drachms. The leucocyte count the day before the injection was 4,000 per cmm, and the day following 19,500 per cmm. The relative percentage of polymorphs rose from 65.5 to 81. This time the patient became very excited fifteen minutes after the injection and screamed violently all day. She spoke a few words, the first she had uttered since admission. She also drank 5 ounces of lemonade the first time she had swallowed anything voluntarily for eight weeks. From this time she made steady progress. On July 14th the arms and legs had relaxed and the splints which had been applied to all four limbs to prevent contractures were removed. After this date the stomach tube was no longer required as she took the food brought to her, and on July 18th she spontaneously asked for drinks.

She was given three more injections of milk on July 12th, 16th, and 21st. The lethargy gradually passed off and her general condition improved. She is still very thin and weak but is regaining muscular power. She is mentally quite clear and amuses herself with reading sewing and writing letters, which in composition and handwriting are above the average.

The blood examinations were made by Dr. J. B. Davey, honorary pathologist to Cheltenham Hospital, and accurate notes of the case were made by the house-physician, Dr. K. F. MacLenzie. Dr. Vaughan has kindly given me the clinical history of the patient when at home.

J. RICHARD COLLINS, M.A., M.D.,
Senior Physician, Cheltenham General and Eye Hospital

AN EPIDEMIC OF MUMPS

The origin and course of a recent outbreak of mumps among the boarders at a boys' public school offered several features of interest.

The epidemic originated with a boy A, aged 16, who during the Easter school holidays went to stay with a friend. Another boy, B, also visited the house, and the two boys went out for the day motor cycling. They were in the open air all the time with the exception of having tea in the house. B was apparently quite well. A returned from the visit, and the next day to boarding school. A letter was received stating that B had developed mumps three days after the motor-cycle ride. A was thereupon sent home from school, and remained away three weeks and three days from the time of contact with B. As no symptoms of mumps had appeared he was allowed to return to school, but four days later (that is, twenty-eight days after contact) he developed the disease, thus the length of the incubation period was clearly twenty-eight days instead of twenty-one as is usually understood, and the infection was contracted by A from B during the prodromal period.

Of one hundred and seventy-five boys fifty developed the disease. As far as could be ascertained, only one had had a previous attack and that had been during the preceding twelve months. Of the boys under 12 years of age only three took the infection.

The general features were slight illness with a temperature not higher than 101° and lasting about three days. There were only two cases of unilateral swelling but several had swelling of the opposite gland a week after the first with a second rise of temperature. There were only three cases of orchitis, which were slight in character. A rather curious feature noted was that several boys developed a form of conjunctivitis. Five boys had high temperatures of 104° and over, and were acutely ill. Their hearts were dilated and a systolic murmur was heard at the apex, and two had an intermittent pulse. Three of the five had a slight scintilliform rash over chest and arms. All the patients were constipated and the stools were of a drabish green colour and very offensive.

From my observations in this epidemic I am led to the following conclusions:

- 1 That mumps may be contracted at any rate at the end of the prodromal period.
- 2 That the incubation period may be as long as twenty-eight days.
- 3 That testicular infection is comparatively rare.
- 4 That some patients may be acutely ill and show symptoms of a general toxic condition.

L. J. C. DICKS, M.B., M.D., B.S.
Framlingham, Suffolk.

Reports of Societies.

ELECTROLOGY A RETROSPECT

IN the Section of Electro-Therapeutics of the Royal Society of Medicine on October 16th the incoming President, Dr ALASTAIR MACGREGOR, delivered his address from the chair. This was entitled "Then and now," and took the form of a retrospect of the developments in the science and art of medicine, and in electriology particularly, which have occurred since he entered Edinburgh University forty-five years ago.

Dr MacGregor reminded his audience that this period had seen the work of Lister complete its triumph, it had seen the birth of bacteriology and biochemistry, the opening out of vast new fields to pharmacology and therapeutics, and, among the more recent developments, the discovery of x-rays and of radium. After giving some account of the progress in general medicine within his own experience and recollection, he described the "suspended animation" of electriology as it was at the beginning of his professional career. His first recollection of any electrical apparatus was the faradic battery, which was used—sometimes, he feared, too vigorously—for Saturday-night "drunks," cases of hysteria, and cases of opium poisoning. It was also used for the treatment of muscles wasted by prolonged application of splints in cases of fracture. He could not remember in those days seeing any galvanic battery at the hospital, and he doubted whether any contemporary of his had more than a hazy recollection of such an apparatus or of its use in the schools.

The President described the familiar landmarks in the progress of electriology, down to the most modern applications of diathermy, and also the development of x-ray work, down to the most recent introduction of high-voltage therapy. He added that in his opinion electriology and radiology would be of still greater value in all branches of medicine and surgery if every properly qualified electriologist and radiologist holding hospital appointments was regarded by the physicians and surgeons as a learned colleague and not merely as a technician. Another reflection which occurred to him, after looking back over almost half a century, was that while some present-day juniors might think that the teachers in those bygone years must have been a very ignorant set of men, this was by no means the case: those teachers not only knew all that was to be known in their time, but they knew how to teach. They did not deserve the gibe, which he thought was coined by Bernard Shaw "Those who know, do, those who don't, teach." Those old teachers, although working under such limited conditions, and unaware of so much that had since been discovered with regard to their subjects, taught their students to use their powers of observation and all the wit with which Nature had endowed them. There had been great advances in technique since they practised and taught, but if the fundamental value of accurate clinical observation and common sense in the interpretation of the results required by technical methods were lost sight of, all those advances would go for nothing. There was, in his opinion, a tendency for the student to give to technique a place too commanding, and thereby to obscure—that those older men with all their limitations clearly saw—that after all it was a human being who was the patient, and that it was necessary to use all their understanding to cure him, or, if that was not possible, to make him as comfortable as they could. The growing habit on the Continent, which showed signs of spreading in this country, was to regard the patient merely as a case—a scientific problem calling for investigation. If the medical man forgot that all the knowledge which had been accumulated, enormous as it had been of recent years, did not suffice to bring him up to the level of any complete understanding of that mass of unstable living material which made up the human being, then he would never, in the real sense of the word, be a master of the art as well as the craft of medicine. The mere collection of disjointed scientific facts, however important, did not confer the divine gift of healing.

MEDICINE AND INDUSTRY

At a meeting of the Brighton and Sussex Medical-Chirurgical Society on October 1st, Mr H. J. WALKER delivered his presidential address on the medical aspect of industry.

Mr Walker said that his subject was almost inexhaustible, but it was of great importance and likely to receive much attention in the present Parliament. Though a great deal had been done already to alleviate the conditions of the industrial worker, further work was necessary. Factory legislation was yet young, the first real Factory Act being only introduced by Sir Robert Peel in 1802, although in Elizabeth's reign there had been a Statute of Apprentices, this had been intended to prevent idleness rather than overwork. Sir Robert Peel, Robert Owen, Lord Shaftesbury, and other philanthropists of that time found the conditions of child labour terrible. Working hours were from 6 a.m. until late at night, and very often women and children worked during the night. On inquiring from well-known doctors as to how long and at what age a child should be allowed to work, one stated that children might work twelve hours a day in factories at the age of 10, another that children might be employed at 7 years, while yet another thought that it was quite salutary for children under 10 to work for five or six hours a day. Children had no fresh air, exercise, or free meal time, as food was snatched away during the machine cleaning, and was eaten in unsanitary conditions, often with dust and cotton fluff filling the air. Until the Act of 1844, machinery had not been properly safeguarded and many accidents happened. In a report on a cotton mill in 1838 it was stated that the place was full of young women, many of them expectant mothers and obliged to stand for twelve hours a day. The heat was excessive, the stench pestiferous. Public opinion became aroused, and in 1847 a ten hours day bill was passed, factory inspectors had been appointed shortly before this. These inspectors had to see that no child under 9 worked in factories, and as it was not until 1837 that births were registered, the inspectors had to rely upon certificates from doctors that a child was of the ordinary strength and appearance of 9 years. It was at this point that Mr. Richards decided to appoint a number of surgeons to be exclusively authorized to give certificates. His example was followed by other inspectors, permission being given by the then Home Secretary, Lord Melbourne, and thus the factory surgeon came into being. The post was held directly from the Home Office with no interference from local authorities. Mr Walker then gave an outline of the duties of a factory surgeon.

In March of this year thirty-seven cases of lead poisoning and six of anthrax were reported to the Home Office, in addition, seven cases of lead poisoning were reported amongst house painters and plumbers. Although this number was far below that of previous years, there should be no cases at all. A disease which medical skill could prevent should be eliminated altogether. Industrial lead poisoning was chronic and very insidious in its onset, consequently in its very early stages action could be taken and serious symptoms of poisoning prevented, acute poisoning was hardly known among industrial workers. Lead poisoning might be considered as a chronic form of poisoning by lead carbonate, and was chiefly found among the workers in the vitreous enamelling of metal and glass, the tinning of metal hollow-ware, the manufacture of electric accumulators, paints, colours, and pottery, it also occurred amongst plumbers and men engaged in handling lead in any form. The lead entered the system almost always by inhalation and absorption from either the pulmonary or alimentary tract or from both, it was very doubtful if any lead was absorbed by the skin. It had been stated that most of the cases occurred during the first eighteen months of employment, but Mr Walker had seen cases develop for the first time after fifteen or twenty years, and in all cases the teeth had been exceptionally bad, which rather suggested that the teeth had been the cause of infection. Since the notification of all cases of lead poisoning and the medical inspection of employees in the factories and workshops, not only had the severity of the symptoms decreased, but also the number of cases. It was rare to see the

complete paralysis of the extensor muscles of the arm and hand, the severe cerebral symptoms such as hemiplegia, hemianesthesia, convulsions and coma, optic neuritis, interstitial nephritis, and gout. Most of the cases of lead poisoning that had come under his notice were in men not employed in factories and workshops, but engaged in outside work, such as house decorating and painting. He thought the chief explanation was the strict regulations laid down in the factories with regard to the provision of washing materials, wearing of overalls, and eating meals. These were not applicable to the man who carried on his work some distance from his workshop or home. Food in these cases was eaten with dirty hands, and clothes were not changed. In house decoration also dust was chiefly inhaled through the scraping away of the old paint, and as this paint had lost most of its oil, and sandpaper was used, inhalation of lead under these conditions was a very easy matter. A wet sandpaper was on the market, but did not appear to be very popular with the employees. That lead could be handled with more or less impunity, if due precautions were taken, was shown by the fact that men handling and cutting up lead sheets for several hours during the day continued their work for years with no detriment to their health. Painters, to the speaker's knowledge, had suffered no ill effects although their hands and arms had been covered duly with paint. Lead acetate did not seem to be so poisonous as the carbonate, large doses of the former having been taken with little deleterious effect.

Industrial mercurial poisoning was chronic and insidious, and was caused by want of care in general cleanliness and hygiene. It occurred among those who worked in factories where mercury was used for making such articles as barometers, thermometers, incandescent electric lamps, electric meters, and in furriers' workshops. The danger arose, not only from the handling, but also from the volatilization of the mercury, the latter point was a very important one. Mercury volatilized at the ordinary temperature, and small particles could be inhaled very easily, so a well ventilated factory was one of the first considerations for the health of the workers. Since the men who worked in mercury had been periodically examined no cases of poisoning had occurred, and the general health of the men had been good. The men were very keen on taking all precautions, especially as regards their teeth, and the teeth seemed to be the most likely point of infection in both lead and mercurial poisoning, in all the cases Mr Walker had seen the teeth had always been eroded and unhealthy.

In one large Brighton factory a room was set aside for first-aid treatment with a trained sister in charge. All employees suffering from the slightest injury reported to the sister, who dressed any wounds and referred patients to their own doctor if necessary. No one was allowed to resume work unless he produced a certificate of fitness from his medical attendant. All working in dangerous trades, such as lead, mercury, and glass-blowing, were given advice as regards treatment, and suspended from their work if necessary. Industrial medicine could effect a saving of many millions a year if properly applied. The Factory Bill now before Parliament suggested that young persons up to the age of 18 should be medically examined before starting work. After that age they were supposed to be capable of looking after themselves, but the exigencies of work, under the present economic system, prevented proper attention being given to health. In all factories and workshops young persons up to the age of 18 should be examined every six months, as unsuitable work at such an age might be the foundation of serious trouble in after life. A health register should be kept with full particulars concerning the employee, the work on which he was engaged, and whether it was suitable or not. All employees should be compelled to seek medical advice for all injuries and diseases of more than a week's duration, and should not be allowed to return to work without a medical certificate of fitness. Examinations should be compulsory every six months in trades in which there was a tendency to undermine the employees' health. There would be hardships in some cases, but the gain to the community at large would far exceed any hardship to the individual. Members of the Navy, Army, Air Force, Post
